proximal to the stricture is carefully dissected circumferentially in a cephalad direction for a distance not to exceed 5 mm. Excessive dissection should be avoided to prevent vascular compromise of this segment of duct, which will be used for the anastomosis. After mobilization and division of the bile duct, the biliary catheters protrude through the proximal end (Fig. 62-9A). A radiologic guide wire is then placed through these catheters. The preoperatively placed catheter can then be exchanged over the wire for a properly sized Silastic stent. These stents are 70 cm long and range from 12 French to 22 French. Multiple side holes are present along 40% of the length of the stent. These side holes are left to reside within the intrahepatic biliary tree and the portion of the Roux-en-Y jejunal limb used for the biliary anastomosis. The end of the stent without the side holes exits through the hepatic parenchyma and is brought out through a stab wound in the upper anterior abdomen. After stent placement, a Roux-en-Y jejunal limb is prepared, and the anastomosis is then performed as an end-to-side hepaticojejunostomy (Fig. 62-9B–D).

The importance of the hilar (epicholedochal) arterial plexus in cases of proximal bile duct injuries is also worth mention. More specifically, performing a “high” hepaticojejunostomy reconstruction to an intact proximal hilar bridge between the right and left hepatic ducts utilizes robust crossing arterial anatomy and is believed by many surgeons to minimize the risk of subsequent biliary stenosis.

An alternative technique has been described for management of bile duct strictures involving the bifurcation and one or both of the hepatic ducts in which a side-to-side anastomosis of the left hepatic duct to the Roux-en-Y limb is constructed. A long opening along the anterior surface of the left hepatic duct is anastomosed to the side of the Roux-en-Y limb. Because it is possible to dissect the anterior surface of the left hepatic duct high up into the hepatic parenchyma, this procedure permits anastomosis to normal mucosa, even though there can be fibrosis and stricture at the bifurcation of the ducts and in the distal portion of the hepatic duct. This technique can avoid the need for postoperative stenting.

Surgical Outcome

Morbidity and Mortality

Repairs of bile duct strictures are performed primarily in major medical centers by experienced surgeons, yet these operations are still associated with significant morbidity and mortality. In 1982, a review of 38 series published since 1900 that included more than 7,643 procedures performed on 5,586 patients reported an overall operative mortality rate of 8.3%.¹⁷ More recently the incidence of operative mortality has decreased markedly with improved technology and a multidisciplinary approach, as well as improved surgical experience. A recent series of 200 consecutive patients managed at the Johns Hopkins Hospital reported three deaths in patients who did not undergo an attempt at repair who were referred with sepsis secondary to an uncontrolled biliary leak, for a mortality rate of 1.5%. Definitive surgical reconstruction was performed in 175 patients with a perioperative mortality of only 1.7%.¹⁸ In this series the timing of repair, the mode of presentation, previous attempts of repair, and the level of injury did not influence outcome. Chronic liver disease can be an important factor for operative mortality and morbidity with advanced biliary cirrhosis and portal hypertension leading to mortality rates approaching 30%. Fortunately in the modern era, such advanced disease is uncommon. In most series postoperative morbidity rates are in the range of 20% to 40%. In the recent Hopkins series, complications occurred in 41% of patients. Most of the complications were minor and could be managed with either interventional radiology techniques or conservative management. No patient required reoperation for postoperative complications. The median length of stay in this series was 8 days.

Figure 62-9. Technique of biliary reconstruction. **A:** A Silastic stent is sutured to the preoperatively placed transhepatic catheter, which protrudes through the transected hepatic duct and through the catheter tract in the hepatic parenchyma. **B:** A Roux-en-Y jejunal loop is then anastomosed to the hepatic duct and (**C**) the Silastic stent is placed through the anastomosis. **D:** A completed Roux-en-Y hepaticojejunostomy with a transanastomotic stent.

Long-Term Results

6 Historically, excellent long-term results were achieved in 70% to 90% of patients who underwent repair of bile duct strictures ([Table 62-2](#)). The definition of satisfactory results in most series requires that patients have no symptoms, jaundice, or cholangitis. Length of follow-up is important in analyzing final results because recurrent strictures can occur up to 20 years after the initial procedure ([Fig. 62-10](#)).^{12,13} Approximately two-thirds of restrictures are evident within 2 years, and 90% are seen within 7 years. The percentage of patients with good results is inversely related to the number of previous repairs. Other factors that favor a good outcome include young age at the time of stricture repair, use of a Roux-en-Y biliary-enteric anastomosis, absence of infection and hepatic fibrosis, and use of transhepatic stents.

As illustrated earlier, in the era before laparoscopic cholecystectomy, excellent long-term results were obtainable in tertiary care centers specializing in the management of these problems. Questions had arisen as to whether the excellent results of bile duct strictures after open cholecystectomy could be directly transferred to patients sustaining laparoscopic bile duct injuries. Some researchers had suggested that the mechanism of bile duct injury during laparoscopic cholecystectomy, the complex nature of many of these injuries, and the frequent association of significant inflammation and fibrosis secondary to sustained, unrecognized bile leakage might result in poor long-term results. Furthermore, the high percentage of these patients who have undergone unsuccessful operations, often performed by the primary laparoscopic surgeon, might also lead to a poor long-term outcome. Evidence for the latter hypothesis was provided by a review of the records of 85 patients who underwent a total of 112 biliary repairs.²⁴ Four factors determined the success or failure of treatment in this series. These factors included performance of preoperative cholangiography, the choice of surgical repair, details of the operative repair, and experience of the surgeon performing the repair. The importance of preoperative delineation of anatomy was clear, in that 96% of procedures in which cholangiograms were not obtained before repair were unsuccessful, and 69% of repairs were not successful when the cholangiographic data were incomplete. When cholangiographic data were complete, the initial repair was successful in 84% of patients. The type of repair was also of significance in influencing outcome. A primary end-to-end ductal repair over a T-tube was unsuccessful in all patients in whom a complete transection of the bile duct had taken place, whereas 63% of Roux-en-Y hepaticojejunostomies were successful. Attempts at repair by the primary surgeon were successful only in 17% of cases, and in no case was a secondary repair by the primary surgeon successful. In those cases in which the first repair was performed by a tertiary care biliary surgeon, a 94% success rate was obtained.

The outcome of management of 142 patients with major bile duct injuries treated during the 1990s has been reported.²¹ Laparoscopic cholecystectomy was the initial operation in 75% of these patients, and 41% had undergone a previous attempt or attempts at surgical repair before referral. In this series with a median follow-up of 58 months (range, 11 to 119 months), a successful outcome was obtained in 91% of patients. In this series the level of injury, clinical presentation, history of prior repair, and length of biliary stenting did not influence outcome. Comparable results have been reported from other high-volume hepatobiliary centers.^{22,25} These results suggest that surgical reconstruction of major bile duct injuries after laparoscopic cholecystectomy can still result in excellent long-term results.

Despite the overall success of biliary reconstruction, there is a small subset of patients with major bile duct injuries in whom standard repair techniques appear to be inadequate. Factors, such as delay in

diagnosis, complex injuries above the hepatic confluence, associated vasculobiliary injuries, and liver atrophy can all negatively affect the outcomes of standard reconstruction. In this select population excellent results have been observed with major hepatectomy.²⁶ A classic example of this scenario would be a patient who has sustained a right posterior sectoral bile duct injury, and subsequent hepatic atrophy with associated recurrent cholangitis. These patients typically benefit most from a right posterior hepatic sectionectomy, as opposed to an attempt at a challenging hepaticojejunostomy reconstruction to a small duct within an abnormal liver. Finally, in rare cases with failure of all standard surgical techniques of reconstruction with resultant end-stage liver disease, liver transplantation may offer the opportunity for survival.²⁷ Interestingly, many of these extreme injuries are caused during open cholecystectomy and therefore, trauma caused by migration from the cystic plate into the hilar plate itself.¹¹

Figure 62-10. The cumulative percentage of recurrent strictures with respect to the time from the initial repair until the next repair. (Adapted from Pitt HA, Miyamoto T, Parapatis SK, et al. Factors influencing outcome in patients with postoperative biliary strictures. *Am J Surg* 1982;144:14–21.)

Although large series from tertiary referral centers have reported excellent long-term results, the overall impact of bile duct injuries on society is significant in terms of health care costs, disability, and even mortality. In an analysis of patients undergoing laparoscopic cholecystectomy from the U.S. Medicare database, Flum et al. demonstrated that the adjusted hazard ratio for death during the follow-up period was significantly higher (2.79, 95% confidence level 2.71–2.88) for patients with a bile duct injury than in those patients without a bile duct injury.²⁸ The hazard increased with advancing age and comorbidities and decreased with the experience of the repairing surgeon. The adjusted hazard of death during follow-up was 11% greater if the repairing surgeon was the same as the injuring surgeon. These data certainly further support the referral of most patients with bile duct injuries to centers with greater experience in the management of the injuries.

Finally, although the overall success of the surgical management of laparoscopic bile duct injuries associated with laparoscopic cholecystectomy is excellent, there is an impression that patients may have an impaired quality of life even after successful repair of their bile duct injury. Quality-of-life assessments after laparoscopic cholecystectomy bile duct injury have been addressed in several recent reports.^{29,30} These results have generally reported either comparable or mildly diminished quality of life compared with matched controls. Interestingly, in one study, patients who reported pursuing a law suit following their injury had significantly worse quality-of-life scores in all domains when compared to those who did not entertain legal action.²⁹ The most recent study, which spanned a 23-year period (169 month median follow-up), evaluated 62 patients who had generally undergone a Roux-en-Y hepaticojejunostomy (86%) reconstruction, confirmed that mental health concerns were more common place than physical or general health issues following bile duct injuries. While most patients displayed an eventual return to their physical baseline, psychological quality of life was much more difficult to correct over time.³¹

Nonoperative Management

Operative management of bile duct strictures is technically difficult and continues to be associated with significant postoperative morbidity and mortality. Moreover, in all series, recurrent strictures develop in a proportion of patients. These factors, in addition to technical advances in the fields of therapeutic radiology and endoscopy, have led to the development of nonoperative techniques for management of bile duct strictures. The optimal method for management using these techniques is dependent on the

presence and anatomy of biliary-enteric continuity.

Percutaneous Balloon Dilation

The management of benign bile duct strictures using the percutaneous transhepatic route is indicated primarily in patients with a failed prior biliary-enteric anastomosis to a jejunal limb. The procedure in many cases can be performed with a combination of local anesthesia and intravenous sedation. In this technique, access to the proximal biliary tree is gained and the stricture is traversed with a guide wire under fluoroscopic guidance. At this point, the stricture is dilated using angioplasty-type balloon catheters, chosen on the basis of the location of the stricture and the diameter of the normal duct (Fig. 62-11). After the procedure, a transhepatic stent is left in place across the stricture to allow access to the biliary tree for follow-up cholangiography, repeat dilation, and maintenance of a lumen during the healing process. In most series, numerous dilations are required.

The results from a number of series have been encouraging (Table 62-3). In a multicenter review of bile duct strictures treated in the open cholecystectomy era, 3-year follow-up showed a 67% patency rate for anastomotic and a 76% patency rate for iatrogenic primary bile duct strictures, yielding an overall 70% success rate.³² A report of 51 patients with bile duct strictures after laparoscopic cholecystectomy managed with percutaneous dilation showed a success rate of 58% with a mean follow-up of 76 months.³³

Complications of balloon dilation are frequent. Cholangitis, hemobilia, and bile leaks can occur in up to 20% of patients. Bleeding, usually from the hepatic parenchyma, has been reported, with transfusions often necessary. Sepsis due to cholangitis can occur despite antibiotic prophylaxis. Sepsis and significant bleeding seldom occur in patients dilated by a T-tube tract, suggesting that much of the morbidity is the result of traversing the hepatic parenchyma by the large percutaneously placed catheters.

Endoscopic Balloon Dilation

Endoscopic balloon dilation is often considered technically possible only in patients with primary bile duct strictures or with strictures at a prior primary end-to-end repair or choledochoduodenal anastomosis. With the advent of double-balloon enteroscopy however, more patients are now able to undergo endoscopic retrograde cholangiopancreatography (ERCP) following preceding hepaticojejunostomies, as well as a myriad of bariatric procedures. In select cases, laparoscopic assisted ERCP is also possible. This technique begins with ERC and endoscopic sphincterotomy. The stricture is traversed retrograde with an atraumatic guide wire, and sequential balloon dilation is used. Reevaluation with cholangiography is performed every 3 to 6 months. Redilation is performed as necessary. In most cases, an endoprosthesis is left in place after dilation for at least 12 months.

Benign postoperative biliary strictures: operate or dilate? *Ann Surg* 1989;210:417–425; discussion 426–427.)

7 The reported experience with endoscopic dilation of benign bile duct strictures is shown in [Table 62-4](#). The largest experience comes from the group in The Netherlands who recently reported their experience in 110 patients.³⁴ The mean number of stents placed was two, the mean duration of stenting was 11 months, and stent-related complications occurred in 33% of patients with one death. Twenty percent of patients were eventually referred for surgery. The overall reported success rate was 74% with a mean follow-up of 7.6 years. A similar experience was reported in the United States.³⁵ In this series, 18 of 25 strictures were postoperative. Strictures were located at the cystic duct junction in 17 patients and in the distal bile duct in the remaining eight patients. Of 25 patients, 22 (88%) had significant clinical benefit from the therapy. Only two complications occurred in this series – one case each of pancreatitis and cholangitis.

Comparative Data

Comparison of results of nonoperative dilation with those of surgery has been difficult. Few centers

have significant experience with both operative and nonoperative management. Furthermore, the definition of a successful procedure, the reporting of complications, and the length of follow-up has not been consistent in the literature. There are no prospective randomized studies to compare these techniques; however, three retrospective comparative studies exist. In the first study, a retrospective review of the results at the Johns Hopkins Hospital between 1979 and 1987 compared percutaneous balloon dilation and surgery in 43 patients with benign postoperative bile duct strictures.¹⁹ Twenty-five patients underwent surgical repair with Roux-en-Y hepaticojejunostomy with postoperative transhepatic stenting for a mean of 13 ± 1.3 months. Twenty patients had percutaneous balloon dilation, a mean of 3.9 times, and were stented transhepatically for a mean of 13.3 ± 2 months. Three patients were managed with both surgery and balloon dilation. The two groups were similar with respect to multiple parameters that might have influenced outcome, including age, sex, associated medical problems, and presentation with either obstructive jaundice or biliary fistulas. No patients died after any of the procedures. Procedure-related morbidity occurred in 20% of surgical patients and in 35% of the patients undergoing balloon dilation. For both groups, a successful outcome was defined as no evidence of cholangitis or jaundice requiring another procedure more than 12 months from the onset of treatment. A failed treatment was defined as the need for crossover to the other treatment modality, either operation or dilation, or late death from liver failure, biliary sepsis, or portal hypertension. A successful repair was achieved in 89% of the surgical patients and in only 52% of the balloon dilation patients (Fig. 62-12). The overall late mortality rate in this series was 10%. One late death occurred in the surgical group, whereas three late deaths followed balloon dilation (4% vs. 15%, respectively). No deaths, however, were attributed to liver failure, biliary sepsis, or portal hypertension associated with the bile duct stricture.

Table 62-4 Results of Endoscopic Balloon Dilatation of Bile Duct Strictures

Investigators	Patients	Success (%)	Follow-Up (mo)

Pitt et al., 2013 ²³	115	76	

To define further the relative benefits of the two procedures, total hospital stay and total procedural costs were determined. As expected, initial hospitalization was longer for surgery than for balloon dilation. When rehospitalization for further dilation, complications, or recurrences was considered, total hospital stay did not differ significantly between the two groups. Cost data paralleled hospitalization data and did not differ significantly between the groups. Thus, the authors concluded that until properly designed, randomized, prospective, controlled trials can be performed, surgical repair for benign postoperative strictures appears to be associated with fewer problems and a greater success rate.

Figure 62-12. Actuarial success rates over 72 months for surgery (89%) and balloon dilation (52%). The difference is statistically significant ($p < 0.01$). (Adapted from Pitt HA, Kaufman SL, Coleman J, et al. Benign postoperative biliary strictures: operate or dilate? *Ann Surg* 1989;210:417–425; discussion 426–427.)

In the second comparative study, the group from The Netherlands compared endoscopic versus surgical treatment of benign bile duct strictures.²¹ Thirty-five patients were treated surgically, and 66 were treated by endoscopic stenting. Patient characteristics, initial injury, previous repairs, and the

level of obstruction were comparable in both groups. Surgical therapy consisted of Roux-en-Y hepaticojejunostomy, and endoscopic therapy consisted of placement of an endoprosthesis with trimonthly elective exchange for 1 year. Successful stent placement was accomplished in 94% of patients managed endoscopically. Six of the 66 endoscopic patients, however, underwent surgical reconstruction either for failed stent placement or for other reasons. Early complications occurred more frequently in the surgically treated group (26% vs. 8%; $p < 0.03$). However, the only procedure-related death occurred in a patient in whom severe pancreatitis developed after endoscopic stent placement. Late complications, which included primarily episodes of cholangitis, occurred only in the endoscopic group (27%). The overall complication rates, therefore, were similar at 26% for surgical patients and 35% for endoscopic patients. The mean follow-up and definition of success were similar to those in the aforementioned study. After surgery, excellent results were observed in 83% of patients, with a recurrent stricture developing in six patients at a mean of 40 months after the initial operation. After endoscopic stenting, excellent results were observed in 72% of patients, with resticture developing in 18% of patients at a mean of 3 months after stent removal. The investigators concluded that endoscopic stenting should be considered for the initial attempt at definitive management in suitable patients in the hope of avoiding reoperation.

The final and most recent comparative study describing 528 patients over 18 years has confirmed a number of interesting observations.²³ More specifically, patients with all types of bile duct injuries were most commonly treated by endoscopists (40%), followed by surgeons (36%) and interventional radiologists (24%). Success rates however were higher for surgery (88%) compared to either endoscopy (76%) or interventional radiology (50%). This observation was accomplished with an overall morbidity amongst the surgical cohort of 24% with no 90-day mortality. Not surprisingly, outcomes also improved dramatically over time amongst all approaches. Although the reason for this progress is clearly multifactorial, issues such as improved selection of patients for each approach, increased experience in reconstruction at the surgeon level (and therefore, fewer surgeons performing repairs overall), and perhaps pursuit of more proximal biliary-enteric anastomoses and/or more selective use of transhepatic stents may each play a role. Taken as a whole, this modern analysis of bile duct injuries confirms the importance of ensuring significant clinician experience with this complication, a multidisciplinary team comprised of HPB surgeons, interventional endoscopists and interventional radiologists, and thoughtful selection of a given patient for the appropriate therapeutic option with the highest chance of long-term success.

Table 62-5 Diseases Associated with Primary Sclerosing Cholangitis

Disease	Frequency (%)
Ulcerative colitis	40–60

Sarcoidosis	Rare
Angioimmunoblastic lymphadenopathy	Rare
Acquired immunodeficiency syndrome	Rare

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis is an idiopathic disease characterized by intrahepatic and extrahepatic inflammatory strictures of the bile ducts that cannot be attributed to other specific causes. The cause of primary sclerosing cholangitis is unknown. Many experts consider primary sclerosing cholangitis to be an autoimmune reaction because it is associated with other autoimmune diseases, such as ulcerative colitis, retroperitoneal fibrosis, and Riedel thyroiditis (Table 62-5). It is likely that a number of causes, including viral or bacterial infections, toxic drug reactions, and congenital anomalies, can all result in

the same end-stage injury that is recognized as primary sclerosing cholangitis.

The usual clinical presentation of patients with primary sclerosing cholangitis involves intermittent jaundice, which begins insidiously in the fourth or fifth decade of life. Right upper quadrant pain, pruritus, fever, weight loss, and fatigue can also occur. The disease is characterized by cyclic remissions and exacerbations. Despite the nomenclature, acute cholangitis is uncommon without previous biliary manipulation or surgery. The diagnosis is suggested by clinical presentation associated with cholestatic liver function test abnormalities. The levels of bilirubin often fluctuate with respect to the remissions and exacerbations of the disease and the extent of hepatic injury. Alkaline phosphatase is usually elevated out of proportion to the serum bilirubin, and is a more persistent finding. The diagnosis, however, usually is confirmed by cholangiography, which reveals multiple dilatations and strictures (beading) of the intrahepatic and extrahepatic bile ducts (Fig. 62-13). MRCP has become the preferred procedure as it is noninvasive. ERC, however, remains an important tool for both diagnostic and therapeutic procedures. An important distinction must be made as cholangiocarcinoma must be considered in the differential diagnosis of a dominant stricture. Furthermore, cholangiocarcinoma may develop after presentation in up to 30% of patients with primary sclerosing cholangitis. Therefore, endoscopic brushings and biopsies are frequently required. The disease should be followed closely by cholangiography and liver biopsy to provide appropriate management before the development of biliary cirrhosis.

Figure 62-13. A: Cholangiogram of a patient with primary sclerosing cholangitis. Multiple irregular strictures and dilatation (beading) of intrahepatic bile ducts can be seen. B: Endoscopic retrograde cholangiogram showing extensive involvement of extrahepatic bile duct (BD) with primary sclerosing cholangitis. (B reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL. Primary sclerosing cholangitis. *Surg Clin North Am* 1990;70:1390.)

No known specific medical therapy is effective for primary sclerosing cholangitis. The most encouraging results, from a prospective, randomized, placebo-controlled trial, suggest that ursodeoxycholic acid significantly improves serum liver function tests and liver histologic appearance. Unfortunately, there were no significant differences in clinical outcome between the two groups at up to 6 years of follow-up.³⁶ Nonoperative dilation therapy by the endoscopic route has been used for dominant strictures with favorable results.³⁷

8 An aggressive surgical approach is advocated for selected symptomatic patients with primary sclerosing cholangitis because of the lack of effective medical therapy. One surgical approach, in patients with a dominant stricture at the hepatic duct bifurcation, uses resection of the bifurcation and long-term transhepatic stenting with Silastic stents. This mode of therapy was recently reported in 77 patients with resection of the hepatic duct bifurcation, with hepatic lobectomy performed in another four patients.³⁸ The perioperative complication rate was 39% and 30-day mortality was 3.9%. Bilirubin

improved and 57% of patients had no primary sclerosing cholangitis–related readmissions. At median follow-up of 10.5 years, the 5- and 10-year survival rates were 76.4% and 52.7%, respectively. Cholangiocarcinoma did not develop in any patients and only seven required liver transplant. Over the same period, liver transplant was performed in 49 patients with cirrhosis with a 10-year survival of 57%.

The role of biliary surgery in primary sclerosing cholangitis, however, has decreased considerably with the growing success of liver transplantation. Primary sclerosing cholangitis has become one of the most common indications for liver transplantation in the United States, with 5-year actuarial survival and graft survival rates of 85% and 72%, respectively.³⁹ Liver transplantation should be considered before the disease is too advanced. The development of a poor quality of life as a result of disabling fatigue, intractable pruritus, severe muscle wasting, and chronic or recurrent bacterial cholangitis or persistent elevations in serum bilirubin are primary indications for referral for liver transplantation.

Preoperative recognition of cholangiocarcinoma is extremely important in this population in that the development of this complication significantly worsens the result after liver transplantation. The presence of known malignancy results in patients being refused transplantation. The microscopic identification of intrahepatic cholangiocarcinoma in the absence of lymph node involvement, often demonstrated in the explanted liver specimen, however, does not usually portend a poor prognosis. Although it can be extremely difficult to confidently confirm or refute the presence of cholangiocarcinoma in this setting, both MRCP and more recently SpyGlass cholangioscopy during ERCP can be extremely helpful. SpyGlass cholangioscopy in particular provides the advantage of direct visualization of the biliary mucosa/lesion, as well as an opportunity for biopsy.

Patients with primary sclerosing cholangitis have a significantly higher rate of development of nonanastomotic biliary strictures after liver transplantation, with histologic features on posttransplantation biopsy consistent with recurrence of the disease. Other causes of stricture, such as hepatic artery thrombosis, preservation-related ischemia, cytomegalovirus infection, and chronic ductopenic rejection, can cause similar lesions. Recurrent primary sclerosing cholangitis usually does not have an aggressive course.

Resection of the hepatic duct bifurcation and long-term transanastomotic stenting in selected patients can preclude or delay the need for hepatic transplantation. Moreover, this operation does not eliminate or influence the results of hepatic transplantation. Resection of the hepatic bifurcation and long-term transhepatic stenting can be recommended for selected patients with primary sclerosing cholangitis with severe strictures at or distal to the hepatic duct bifurcation but without established biliary cirrhosis. In patients with biliary cirrhosis, hepatic transplantation is recommended.

BILE DUCT STRICTURES SECONDARY TO CHRONIC PANCREATITIS

9 Chronic pancreatitis is an uncommon cause of benign bile duct strictures, resulting in less than 10% of such cases. Transient partial obstruction of the distal common bile duct caused by inflammation and edema frequently occurs in patients with acute pancreatitis. With chronic pancreatitis, however, the clinical problem is distal bile duct obstruction caused by inflammation and parenchymal fibrosis of the gland. These strictures classically involve the entire intrapancreatic segment of the common bile duct and are associated with dilatation of the entire proximal biliary tree (Fig. 62-14). In most cases, the cause of the chronic pancreatitis is alcoholism. Often, advanced disease is present in that the incidence of pancreatic calcification, diabetes, and malabsorption is increased at the time of presentation with jaundice compared with patients with chronic pancreatitis without jaundice. Common bile duct strictures have been reported to occur in 3% to 29% of patients with chronic alcoholic pancreatitis. In a review of a number of clinical series, the overall incidence of common bile duct strictures in patients with chronic pancreatitis was 5.7%.⁴⁰ The exact incidence of common bile duct strictures is not known, however, because cholangiography is not routinely performed in patients with chronic pancreatitis.

The clinical presentation of patients with common bile duct strictures secondary to chronic pancreatitis is variable. Some patients have no symptoms, with the diagnosis of bile duct strictures suggested only by abnormal liver function test results. The serum alkaline phosphatase appears to be the most sensitive laboratory finding and is elevated in more than 80% of patients. Abdominal pain with or without jaundice is another common presentation. In some cases, the abdominal pain can be difficult to distinguish from the pain associated with chronic pancreatitis. Failure to recognize and address a bile duct stricture, however, can lead to ultimate failure of operative procedures performed for chronic pain in patients with chronic pancreatitis. Finally, the development of jaundice in patients with chronic

pancreatitis must be differentiated from underlying periampullary malignancy.

Figure 62-14. Actuarial survival rates among 31 noncirrhotic patients with primary sclerosing cholangitis who underwent resection of the hepatic bifurcation and long-term transhepatic stenting. (Reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL. Primary sclerosing cholangitis. *Surg Clin North Am* 1990;70:1381–1402.)

The definitive evaluation of patients with a bile duct stricture caused by chronic pancreatitis is cholangiography. Either MRCP or ERCP is the preferred diagnostic procedure as they both can demonstrate both biliary and pancreatic ductal anatomy, which is essential in optimal surgical management of chronic pancreatitis. ERCP with stenting allows decompression of the obstructed biliary tree if necessary for cholangitis or severe jaundice. A long (usually 2- to 4-cm), smooth, gradual tapering of the common bile duct is most compatible with a benign stricture due to chronic pancreatitis (Fig. 62-15).

The indications for surgical management of common bile duct strictures due to chronic pancreatitis are clear in patients with significant pain, jaundice, or cholangitis. Controversy exists, however, concerning the necessity of biliary decompression in patients with an asymptomatic elevation of serum alkaline phosphatase. In general, biliary bypass is indicated because changes from obstructive biliary cirrhosis have been observed in liver biopsy specimens obtained from patients with long-standing, functionally significant biliary obstruction due to chronic pancreatitis.^{41,42} Some clinicians may also consider biliary dilatation and temporary intraluminal stenting in this setting using either endoscopic (preferred) or percutaneous approaches.

Choledochoduodenostomy and Roux-en-Y choledochojejunostomy are acceptable methods of biliary bypass in patients with bile duct strictures caused by chronic pancreatitis. Choledochoduodenostomy is preferred by many surgeons because it does not divert bile from the duodenum, is technically easier to perform, and leaves the jejunum intact for any associated procedures required for decompression of an obstructed gastrointestinal tract or pancreatic duct. Finally, in patients in whom periampullary malignancy cannot be completely ruled out by the clinical course or imaging studies, or in patients with significant chronic pain thought secondary to proximal pancreatic duct disease, pancreaticoduodenectomy offers an excellent treatment option. The results of surgical management of distal bile duct structures due to chronic pancreatitis are usually excellent, with a low rate of perioperative complications and excellent long-term results.

Figure 62-15. Cholangiogram of a patient with a long distal common bile duct stricture (*arrow*) caused by chronic pancreatitis.

Transduodenal sphincteroplasty is not recommended for the management of common bile duct strictures caused by chronic pancreatitis because the stricture is too long to be managed adequately by this technique. Similarly, endoscopic sphincterotomy has no role in the management of biliary obstruction due to chronic pancreatitis. Limited experience has been reported with balloon dilation of distal bile duct strictures secondary to pancreatitis, with little long-term follow-up.

Over the last decade another variant of chronic pancreatitis has been recognized as a cause of distal bile duct stricture – autoimmune pancreatitis.⁴³ This process is characterized by a lymphoplasmacytic infiltrate and is associated with secretion of large amounts of immunoglobulin (Ig) 4. The condition can mimic pancreatic cancer and is diagnosed by characteristic imaging studies and elevation of serum Ig4 levels. Treatment is with corticosteroids with surgical resection or bypass reserved for unresponsive cases or when a diagnostic dilemma remains. Although Ig4 serology is highly sensitive (90%), cases where equipoise remains can also undergo an initial empiric test of corticosteroids to assist in achieving the diagnosis and potentially provide concurrent therapy.

MISCELLANEOUS CAUSES OF BILE DUCT STRICTURES

Benign strictures of the bile duct can result from the chronic inflammation associated with gallstones in either the gallbladder or common bile duct. This cause of bile duct strictures is uncommon and is a rare complication of gallstone disease. Bile duct strictures caused by cholelithiasis are usually associated with a narrowing at the level of the common hepatic duct caused by a stone impacted in the infundibulum of the gallbladder. The narrowing can be caused by two means. First, simple compression can occur from a large stone lying adjacent to the common hepatic duct (Mirizzi type A). Second, chronic or acute inflammation arising from the gallbladder or cystic duct can extend to the contiguous bile duct, resulting in stricture formation (Mirizzi type B, C, or D). The biliary obstruction associated with either of these conditions is known as *Mirizzi syndrome* and culminates in Mirizzi type E disease which occurs in any case of bilioenteric fistula.⁴⁴

The clinical presentation of a bile duct stricture caused by cholelithiasis is often associated with acute cholecystitis and hyperbilirubinemia. In some long-standing cases, these findings exist in the face of chronic gallbladder symptoms. If hyperbilirubinemia is present and urgent cholecystectomy is not indicated, ERCP or PTC can help to delineate the preoperative biliary anatomy. Most cases that are associated with acute cholecystitis, however, are recognized at the time of cholecystectomy and operative cholangiography. When the duct compression is associated with acute inflammation, the common hepatic duct almost always returns to normal after the offending stone has been removed by cholecystectomy and the inflammatory process has resolved. Care must be taken during the dissection

to avoid creation of a defect in the common hepatic duct. Rarely, after the acute episode has resolved, a well-established stricture presents months to years after the acute episode. In such cases, management by Roux-en-Y hepaticojejunostomy is appropriate.

Strictures due to choledocholithiasis are also rare. The presumed mechanism is erosion of the epithelium of the distal duct, creating inflammation with subsequent fibrosis and stricture. Because of the anatomic tapering of the common bile duct, nearly all stones are entrapped in the intrapancreatic portion of the duct and are often difficult to remove by the supraduodenal route.

Excessive intraoperative manipulation at the time of bile duct exploration with forceps, scoops, and catheters can often create additional trauma to an already friable distal duct. After the stone has been removed, the distal bile duct should be gently sized with a soft rubber catheter to be sure that no stricture exists. If a stricture persists after stone removal, it may not be recognized until the time of postoperative T-tube cholangiography. If recognized in the postoperative period, time should be allowed for resolution of inflammation before considering stricture repair. If a distal bile duct stricture does persist, a biliary-enteric anastomosis with either Roux-en-Y choledochojejunostomy or a choledochoduodenostomy is indicated. If the proximal duct is adequately dilated (>2 cm in diameter) to allow a large choledochoduodenal anastomosis, this procedure is usually preferable because of its technical ease and excellent results.

Stenosis of the sphincter of Oddi, or papillitis, is a benign intrinsic obstruction of the outlet of the common bile duct, usually associated with inflammation, fibrosis, or muscular hypertrophy. Sphincter stenosis can result in any of three clinical conditions: (a) common bile duct obstruction due to fibrotic stenosis of the papilla, (b) recurrent pancreatitis, or (c) recurrent right upper quadrant pain without jaundice or pancreatitis. The pathogenesis of the inflammation of sphincter stenosis is unclear. In many cases, it is thought to result from the trauma of the passage of multiple small stones from the common duct through the ampulla. This trauma results in inflammation, scarring, and stricture formation. Many patients with papillary stenosis have no gallstones. Other potential mechanisms include primary sphincter motility disorders and congenital anomalies. The clinical presentation is usually either jaundice or cholangitis. In some cases, an impacted common bile duct stone may be present. The diagnosis can be supported with either PTC or ERC. This condition can be managed by sphincterotomy performed either endoscopically or operatively. If a cholecystectomy was performed previously, endoscopic papillotomy is the initial procedure of choice.

Cholangiohepatitis is an unusual infection of the biliary tree frequently associated with *Clonorchis sinensis* and other parasites. These infections are most commonly seen in natives of Asia. Most patients present with recurrent episodes of cholangitis. Cholangiography can demonstrate multiple strictures of both the intrahepatic and extrahepatic biliary tree, with the bile ducts filled with sludge and stones (Fig. 62-16). Surgical management consists of cholecystectomy and improved biliary drainage with either Roux-en-Y choledochojejunostomy or choledochoduodenostomy. Access to the biliary tree for postoperative management of intrahepatic stones or sludge should be maintained with either transhepatic biliary stents or a choledochojejunocutaneous or subcutaneous fistula. No specific medical management is available for this condition.

Finally, rare causes of benign intrahepatic and extrahepatic bile duct strictures have been reported secondary to intrahepatic arterial infusion of 5-fluorouracil used in the treatment of hepatic metastases of colorectal carcinoma. The clinical picture closely resembles primary sclerosing cholangitis but usually can be managed by simple discontinuation of infusion and, in some cases, percutaneous transhepatic drainage. Surgery should be reserved for patients with persistent evidence of biliary obstruction. A similar cholangiographic appearance has been reported in patients with acquired immunodeficiency syndrome. The pathogenesis of this injury is believed to be viral and related to cytomegalovirus infection. No experience in the surgical management of this condition has been reported.

Figure 62-16. Cholangiogram of a patient with cholangiohepatitis with diffuse bile duct dilatation. The biliary tree is filled with sludge (SI) and stones.

Chapter 63

Biliary Neoplasms

Kaitlyn J. Kelly, Yuman Fong, and Sharon Weber

Key Points

- 1 Surgery remains the only curative option for biliary malignancies.
 - 2 Gallbladder cancer is a rare malignancy with a dismal prognosis because of its insidious onset, propensity for local invasion, and rapid disease progression.
 - 3 The association of gallstones with carcinoma is probably related to chronic inflammation.
 - 4 Patients with choledochal cysts have an increased risk of carcinoma developing anywhere in the biliary tree, but the incidence is highest in the gallbladder.
 - 5 The only curative option in patients with gallbladder cancer is complete surgical resection.
 - 6 Nonoperative palliative biliary decompression can be accomplished with percutaneous or endoscopic stenting, depending on the level of obstruction.
-

INTRODUCTION

1 Tumors arising in the gallbladder and biliary tree are rare, with approximately 10,650 cases per year in the United States and 140,000 per year worldwide.^{1,2} These tumors are often asymptomatic until late in the course of the disease. Consequently, these tumors commonly present in an advanced, often unresectable stage. Surgery remains the only curative option for biliary malignancies. Complete resection of biliary neoplasms, however, often requires radical resections and complex biliary reconstructions that are only routinely safe at specialized, high-volume centers. Surgery also offers potential for effective palliation of these cancers, including biliary bypasses for jaundiced patients with unresectable tumors. Both the late diagnosis and the complex operative techniques required for potentially curative resection contribute to the challenge of these cases. In addition, there are no proven effective options for adjuvant treatment. This chapter reviews the incidence, diagnosis, and therapy of these malignancies as well as the outcomes of treatment.

GALLBLADDER CARCINOMA

2 Gallbladder cancer is a rare malignancy with a dismal prognosis because of its insidious onset, propensity for local invasion, and rapid disease progression. Overall, most series report a 5-year survival of less than 5%.

Incidence

Gallbladder cancer is the most common biliary tract malignancy, but there are only 6,000 to 7,000 new cases diagnosed nationally each year. Attesting to the rarity of this lesion, after routine screening of abdominal ultrasounds in asymptomatic patients in Japan, only 19 out of 194,767 patients (0.01%) were found to have gallbladder cancer.³ This tumor occurs more frequently in women (female:male ratio = 3:1), and peak incidence is in the seventh decade.⁴ There is a tremendously increased risk of gallbladder cancer, in particular indigenous populations, including Mapuche Indians in South America (12.3 cases/100,000 males and 27.3/100,000 females, and Native Americans in New Mexico (8.9 cases/100,000 people).^{5,6}

The increased risk of gallbladder cancer with cholelithiasis is well established; 70% to 90% of all patients with carcinoma also have gallstones. However, less than 0.5% of patients with gallstones are found to have gallbladder cancer.⁵ In recent series of patients undergoing elective cholecystectomy for gallstones, gallbladder cancer is found incidentally in <0.5% of patients.⁷ The association of gallstones with carcinoma is probably related to chronic inflammation. Larger stones (>3 cm) are associated with

a 10-fold increased risk of cancer.^{6,8}

3 The association of gallbladder cancer with gallstone disease has led some investigators to question whether all patients with gallstones should undergo cholecystectomy. The argument against this approach is that the use of cholecystectomy only for symptomatic patients, thus leaving the gallbladder in place in patients with asymptomatic gallstones, has not led to an increase in the prevalence of gallbladder cancer over time. Also, epidemiologic studies have found that the 20-year risk of developing cancer in patients with gallstones is less than 0.5% for the overall population and 1.5% for high-risk groups.⁵ Thus, routine cholecystectomy for asymptomatic gallstones because of concern for gallbladder cancer does not appear to be warranted.

In the past, the finding of a calcified gallbladder wall, called “porcelain gallbladder” (Fig. 63-1), was associated with a high risk of cancer, in some series ranging from 25% to 60%.⁹ Thus, the recommendation was for all patients with porcelain gallbladder to undergo open cholecystectomy, even if asymptomatic. Recent series evaluating this issue, however, suggest that the risk of gallbladder cancer in patients with porcelain gallbladder has likely been greatly overestimated. In fact, although patients with limited areas of calcification of the wall may have a higher incidence of gallbladder cancer (7%), patients with diffuse calcification of the gallbladder wall, the classic presentation for porcelain gallbladder, do not appear to have an increased risk of gallbladder cancer.^{10,11}

4 Patients with choledochal cysts have an increased risk of carcinoma developing anywhere in the biliary tree, but the incidence is highest in the gallbladder. This risk increases with age. Therefore, cholecystectomy is recommended for all patients with choledochal cysts at the time of diagnosis.

Figure 63-1. Unresectable gallbladder cancer demonstrating palliative transhepatic percutaneous stent placed to relieve jaundice. Porcelain gallbladder is present (arrows).

Pathology and Staging

More than 80% of gallbladder cancers are adenocarcinomas; there are several histologic subtypes, including papillary, nodular, and tubular. Papillary tumors, which grow predominantly into the gallbladder lumen, have an improved prognosis compared with the other subtypes.¹² Poor prognostic signs in gallbladder cancer include grade, and vascular invasion.^{12,13} The most important prognostic factor may be lymph node status, although 5-year survivors with nodal involvement have been documented.^{14,15} Less than 5% of cases are squamous cell carcinomas, with the remaining 10% being anaplastic lesions.

Gallbladder cancer spreads via the lymphatic and venous drainage. Because of drainage of the cholecystic veins directly into the adjacent liver, these tumors often involve hepatic parenchyma, most often portions of segments IV and V. Lymphatic spread is first to the cystic duct (Calot) node, then to pericholedochal and hilar nodes, and finally to peripancreatic, duodenal, periportal, celiac, and superior

mesenteric artery nodes. Nodal disease in the porta hepatis often causes common bile duct (CBD) obstruction and resultant jaundice, which is the first clinical symptom in 30% of patients. Jaundice may also be caused by tumors arising in the infundibulum, which may spread directly to the cystic duct and common hepatic duct. Although peritoneal metastases are frequent, distant extraperitoneal metastases are not.

Limited information exists regarding the genetic changes in gallbladder cancer. Recently reported gene abnormalities associated with gallbladder cancer include p53, K-ras, CDKN2 (9p21), FGFR, and PI3 kinase pathway aberrations.^{16–20} The finding that patients with an anomalous pancreaticobiliary junction have a greater frequency of K-ras mutations has led investigators to believe that reflux of pancreatic enzymes into the biliary tree may contribute to the development of cancer.¹⁶ Because of our limited knowledge of the sequence of molecular changes, there are no known detectors of early disease or of risk assessment. Clearly, this is an area that needs improvement, particularly in endemic areas.

The American Joint Committee on Cancer's (AJCC) seventh edition of its tumor, node, metastasis (TNM) staging system (Table 63-1) reflects prognostic characteristics of tumor depth, regional nodal disease, and distant spread. The gallbladder differs histologically from the rest of the gastrointestinal tract in that it lacks a muscularis mucosa and submucosa. The gallbladder wall is composed of (a) a single layer of columnar cells, the mucosa, and lamina propria; (b) a fibromuscular layer; (c) a perimuscular, subserosal layer containing lymphatics and neurovascular structures; and (d) a serosal surface, except where the gallbladder is embedded in the liver. Because lymphatics are present in the subserosal layer only, tumors invading less than the full thickness of the muscular layer have minimal risk of nodal spread. Thus, disease invading into, but not through, the muscular layer of the gallbladder is T1b disease (stage I), whereas invasion into the perimuscular connective tissue is T2 (stage II). Stage III disease includes tumors that have perforated the serosa or have directly invaded the liver or other surrounding structures (T3), which are clearly more advanced but still potentially resectable. Tumors that invade the main portal vein, hepatic artery, or two or more extrahepatic organs/structures are classified as T4 (stage IVA) and are typically unresectable. Lymph node metastasis to regional, periportal nodes are N1 whereas those to more distant nodes outside of what would be included in a standard resection (celiac, periaortic, and superior mesenteric nodes) are N2. N1 nodal metastasis is classified as stage IIIB and N2 as stage IVB. In line with other pancreaticobiliary malignancies, the stage III grouping refers to locally advanced disease and stage IV indicates metastatic disease.

Clinical Findings and Diagnosis

Most patients are found to have gallbladder cancer during workup or treatment of cholelithiasis or choledocholithiasis. In patients with symptoms, abdominal pain consistent with biliary colic or acute cholecystitis is most common. Patients also present with jaundice, weight loss, anorexia, or an increase in abdominal girth secondary to ascites. Physical findings may include right upper quadrant tenderness or a palpable mass, hepatomegaly, and ascites. Laboratory investigation, if abnormal, is most often consistent with biliary obstruction. Because of its nonspecific presentation and the lack of reliable screening tests, gallbladder cancer is not diagnosed preoperatively in more than half the cases.

Imaging evaluation often reveals a thickened gallbladder wall or a mass within or replacing the gallbladder on ultrasound examination. Because polyps, asymmetric wall thickening from cholecystitis (especially xanthogranulomatous type), and carcinoma can have an echogenicity similar to the gallbladder wall, these lesions are often difficult to distinguish. This is even more difficult when inflammation is present from gallstones. At times, ultrasound can visualize invasion of the liver, adjacent adenopathy, and a dilated biliary tree. The ability of ultrasound to differentiate benign from neoplastic disease is enhanced using endoscopic ultrasound, and may be more specific than computed tomography (CT) or magnetic resonance imaging (MRI).^{21–23}

A dynamic contrast-enhanced CT scan may identify a gallbladder mass or invasion into the liver parenchyma or adjacent organs. The classic finding in a patient with gallbladder cancer is asymmetric thickening of the gallbladder wall. Staging of gallbladder carcinoma using CT, however, is limited by poor sensitivity in identifying nodal spread.²⁴

In patients who are jaundiced, direct cholangiography may be useful to delineate the extent of biliary involvement as well as to palliate symptoms of biliary obstruction. A mid-bile duct obstruction not caused by gallstones is gallbladder cancer until proved otherwise (Fig. 63-2). More recently, with improvements in MRI technology, diffusion-weighted imaging and magnetic resonance cholangiopancreatography (MRCP) have evolved into a single, noninvasive imaging modality that allows complete assessment of biliary, vascular, hepatic parenchymal, and nodal involvement, as well as

involvement of adjacent organs (Fig. 63-3).²⁵⁻²⁷

STAGING

Table 63-1 American Joint Committee on Cancer, 7th Edition, Staging System for Gallbladder Carcinoma

Stage	Tumor	Nodes	Metastasis
0	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
IIIA	T3	N0	M0
IIIB	T1–3	N1	M0
IVA	T4	N0–1	M0
IVB	Any T	N2	M0
	Any T	Any N	M1
Definition of TNM			
Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor invades lamina propria or muscular layer		
T1a	Tumor invades lamina propria		
T1b	Tumor invades muscular layer		
T2	Tumor invades perimuscular connective tissue; no extension beyond serosa or into liver		
T3	Tumor perforates the serosa (visceral peritoneum) and/or directly invades the liver and/or one other adjacent organ or structure, such as the stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts		
T4	Tumor invades main portal vein or hepatic artery or invades two or more extrahepatic organs or structures		
Regional Lymph Nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastases		
N1	Nodes confined to the hepatic hilus (including nodes along the common bile duct, hepatic artery, portal vein, and cystic duct		
N2	Metastases to celiac, periduodenal, peripancreatic, and/or superior mesenteric artery lymph nodes		
Distant Metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis

In patients who present with incidentally discovered gallbladder cancer following cholecystectomy, staging should be performed with high-quality CT or MRI of the chest, abdomen, and pelvis. There is no clear role for PET/CT in this setting.²⁸

Surgery

5 It is clear that the only curative option in patients with gallbladder cancer is complete surgical resection. It is essential for optimal patient care that patients with gallbladder cancer be recognized before laparoscopic cholecystectomy is performed, because of the risk of bile spillage, with its potential for subsequent carcinomatosis.²⁹

Role of Staging Laparoscopy

Because a large percentage of patients with gallbladder cancer are found to have occult, unresectable disease at the time of surgical exploration, several authors have investigated the use of initial staging laparoscopy for this disease.^{30–33} Because gallbladder cancer has such a propensity to spread intra-abdominally, this tumor is ideal for detection of intra-abdominal metastases with laparoscopy. This is demonstrated by the fact that up to 50% of patients are found to have unresectable disease at the time

of laparoscopy.^{34,35} Patients who are found to have unresectable disease at laparoscopy can begin other forms of systemic therapy earlier and may undergo the procedure as an outpatient. Particularly because patients with unresectable disease have a median survival of only 6 months, the impact on quality of life, including decreased length of stay in the hospital, cannot be overemphasized.

Figure 63-2. Endoscopic retrograde cholangiopancreatogram obtained from a patient with gallbladder cancer. Mid-bile duct obstruction (*arrow*) is caused by direct extension of tumor to the cystic and common hepatic duct.

Cholecystectomy With or Without Partial Hepatectomy

Gallbladder cancer, if not completely surgically removed, results in rapid local progression and death. In a collected review of 5,836 patients with gallbladder cancer, the overall mean survival was between 2 and 5 months, whereas the 5-year survival was 4%.⁵ The 5-year survival of patients undergoing resection with curative intent was 17%. Of the 2,115 patients with unresectable disease, only a single survivor was found at 5 years. Although surgical resection represents the treatment of choice and the only potentially curative therapy available, resection is possible in only 25% of patients at presentation because of the advanced nature of the disease.⁵

Figure 63-3. T1-weighted magnetic resonance imaging scan of a patient with gallbladder cancer (*small arrows*) with extension into the duodenum and the hepatic flexure of colon (*large arrows*).

There is little doubt that the results of treatment, as well as the scope of operation, are related to depth of tumor penetration ([Table 63-2](#)). For tumors limited to the muscular layer of the gallbladder

(T1), there is near-universal agreement that simple cholecystectomy is adequate.^{15,36–38} T1 tumors have not yet invaded the subserosal layer, which contains lymphatics, and therefore lymphadenectomy is not required. Attesting to the fact that early gallbladder carcinoma is completely curable, simple cholecystectomy has resulted in 90% to 100% survival when early cancer is an incidental finding after elective cholecystectomy.^{15,47}

Difficulty can arise at the time of surgery in evaluating polypoid lesions of the gallbladder as either benign or early gallbladder cancer. Although it appears that frozen section diagnosis is fairly reliable in distinguishing whether lesions are malignant or benign (95% accurate), the accuracy in correctly assessing depth of invasion is only 70%.⁴⁷ Thus, it may be difficult at the time of surgery to determine the extent of resection. Because of this, pursuing a more aggressive resection if the depth of invasion is in doubt is important for adequate tumor clearance.

The extent of surgical resection for T2 or greater tumors is controversial, with recommendations ranging from simple cholecystectomy to radical excision, including hepatectomy. For advanced local disease, some groups have advocated radical resections, including hepatectomy and pancreatectomy. Whereas it is clear that major hepatic resection can be performed safely with a mortality less than 5% (Table 63-3) it has not been universally accepted that more aggressive resections, such as combined hepatectomy and pancreaticoduodenectomy, improve survival.^{14,15,36,37,40,48}

To understand the rationale for extensive resections, it is also important to understand the pattern of spread of gallbladder cancer. Direct extension to the adjacent liver parenchyma often occurs first, followed by adjacent organ involvement, including duodenum, colon, and stomach (Fig. 63-2). Lymphatic spread of gallbladder cancer is routine, often involving nodes in the porta hepatis, peripancreatic region, celiac axis, and the aortocaval nodal basins. There is currently no consensus on the extent of lymphadenectomy that is appropriate for gallbladder cancer. Extensive lymphadenectomy

including para-aortic nodes is advocated in the East, but is not universally accepted. Recently, a technique of intraoperative nodal staging was proposed that entails sampling the highest peripancreatic lymph node for frozen section. This is the lymph node situated between the N1 and N2 nodal stations at the junction of the bile duct and the superior border of the head of the pancreas (Fig. 63-4). Metastatic disease to this node has been shown to be a poor prognostic factor.⁴⁹

Figure 63-4. Illustration of the highest peripancreatic lymph node.

Because the gallbladder is not surrounded by serosa where it is attached to the liver in the gallbladder fossa, even T2 tumors (full-thickness invasion of the muscular layer into the perimuscular connective tissue, no extension beyond serosa or into liver) can invade the normal plane of dissection in the gallbladder fossa during simple cholecystectomy. Therefore, T2 tumors cannot be completely removed with cholecystectomy alone, and a radical cholecystectomy, with resection of a 1- to 2-cm rim of normal liver around the gallbladder fossa, is the minimal resection that is required. Many authors, however, have found that segmental resection of segments IVb and V of the liver, which abut the gallbladder fossa, results in a more anatomically controlled dissection with less blood loss.⁵⁰ An additional part of the definitive surgical treatment is regional lymphadenectomy, because about half the patients with T2 tumors are found to have nodal spread after resection.¹⁴ Dissection of lymph nodes should include all tissues from the bifurcation of the hepatic ducts to the distal CBD. Proponents of this approach advocate liver resection on the basis that it is the only way to obtain an adequate margin on the hepatic side of the gallbladder and resection of the regional nodes allows the best chance for complete tumor clearance. For all of these reasons, simple cholecystectomy is inadequate for T2 or greater tumors. When larger anatomic hepatic resections have been performed in patients with T2 tumors, it has increased the 5-year survival from 25% to 40% after simple cholecystectomy to 70% to 100% after radical resection.^{14,36-38,39,43,44,51,52}

For T3 and T4 lesions, there is a high likelihood of intraperitoneal and hematogenous spread and significant morbidity from the radical procedures that are often necessary for excision of local disease. Recent series, however, support an aggressive approach to resection of these large tumors, particularly if no indication of nodal involvement is found (Table 63-3). For T3 and resectable T4 tumors, a minimal resection includes segments IVb and V, and in many cases an extended right hepatectomy (segments IV, V, VI, VII, and VIII) may be necessary to obtain complete resection. With aggressive resection, long-term survival can be achieved even for patients with these more advanced tumors.^{14,15,36,37,40,53}

Surgical exploration should be performed for all patients without medical contraindications. If a T1 tumor is suspected, a cholecystectomy and biopsy of regional nodes should be performed after thorough examination of the abdominal cavity for any signs of tumor dissemination. The pathology and depth of penetration should be confirmed by frozen section, and the procedure terminated if a T1 tumor with negative margins is confirmed. For T2 lesions, either a radical cholecystectomy (wedge resection of the hepatic bed) or a segment IVb and V resection with lymphadenectomy should be performed.¹⁴ For T3 lesions, a segment IVb and V resection or extended right hepatectomy is performed. Finally, for T4 lesions, a more radical excision of the liver, such as extended right hepatectomy, usually must be performed for adequate tumor clearance.

Tumor location may be important in determining the extent of resection. If the tumor arises in the gallbladder infundibulum, the CBD is often involved with tumor, either by direct extension or external invasion of the hepatoduodenal ligament. In this case, an extended liver resection and removal of a portion of the CBD should be performed. Reconstruction is then performed by Roux-en-Y hepaticojejunostomy. Tumor arising in the fundus of the gallbladder, however, can be treated with limited hepatic resection without excision of the CBD. Complete regional lymphadenectomy should be performed, skeletonizing the CBD, hepatic artery, and portal vein. Short-term postoperative outcomes following resection of gallbladder cancer have remained relatively stable over time, with postoperative morbidity occurring in 30% to 40% of patients, and mortality occurring in <5% (Table 63-4).

Incidentally or Laparoscopically Discovered Gallbladder Cancer

Gallbladder cancer is often discovered during pathologic examination after cholecystectomy for presumed benign disease. Because of the popularization of laparoscopic cholecystectomy in the past decade, an increasing number of patients with gallbladder cancer are found incidentally. Patients with T1b or greater tumors and no signs of distant disease should be offered exploration and further resection to eradicate all diseases. In a series of 135 patients who underwent reexploration following laparoscopic cholecystectomy, 61% of all and 36% of those with T1b primary tumors were found to have residual disease.⁵⁴ In this study, survival following reresection of residual locoregional disease was extremely poor and was not different from that of patients with metastatic disease. Improved survival has been demonstrated following reresection to achieve negative margins, however, especially in patients with T2 or T3 disease.^{51,55,56} While laparoscopic port-site recurrence has been reported, it is associated with peritoneal-based disease. Port-site excision at the time of reexploration is no longer recommended as recent data have shown that it is not associated with decreased recurrence or improved survival.^{57,58}

Reresection after recent cholecystectomy is often technically challenging. Postoperative inflammation in the right upper quadrant often hinders distinction of tumor from normal tissue. Bile spillage at the time of the initial operation may result in carcinomatosis.⁵⁹ Determination of ductal or nodal involvement by tumor is always difficult at the time of reoperation. In addition, postoperative fibrosis often encases the right hepatic artery, which crosses behind the bile duct in most patients. Because of this, during a second operation for incidentally discovered gallbladder cancer, an extended right hepatectomy along with excision of the extrahepatic biliary tree and portal lymphadenectomy is often necessary. This resection allows adequate exposure for lymphadenectomy and greater confidence of a negative margin on the bile duct, and also permits biliary reconstruction to only one side of the liver. The disadvantage is that a large portion of normal liver parenchyma is sacrificed, and consequently, transient postoperative liver dysfunction is common. Although it may be more difficult to curatively resect disease in patients with incidentally discovered gallbladder cancer after laparoscopic cholecystectomy, there is no difference in overall survival between patients with incidentally discovered gallbladder cancer who are submitted to curative resection and those patients who undergo initial curative resection.⁵⁰

When a patient presents with T1a gallbladder cancer discovered after simple cholecystectomy, the pathology should be reviewed to determine if the entire gallbladder has been removed and if the cystic duct margin is clear of tumor. If the cystic duct margin is positive, the patient requires bile duct excision. If all margins are negative, no further therapy is warranted. If the tumor is proved to be T1b or greater, complete staging should be performed. In the absence of metastatic disease, patients should be counseled regarding reexcision to attempt complete resection, chemotherapy with or without radiation, or observation. Patients with a known or suspected early gallbladder carcinoma should be referred to an experienced center where curative-intent resection can be performed at the initial operation.

Adjuvant Therapy

Adjuvant therapy for gallbladder cancer remains a controversial and unproved consideration and is rarely utilized.⁴⁵ Very few randomized trials have been completed, and the conclusions that can be drawn from them are limited given the small sample sizes. Given the relative rarity of these malignancies in the United States, large-scale, randomized trials are feasible only in the context of a multi-institutional or cooperative group setting.

In 2002, a randomized phase III trial of adjuvant chemotherapy with 5-fluorouracil and mitomycin C versus surgery alone for patients with pancreaticobiliary malignancies having resection found that in the

subset of patients with gallbladder cancer ($n = 112$), the 5-year survival rate was significantly better in the adjuvant group (26%) versus the control group (14%).⁶⁰ Similarly, the 5-year disease-free survival rate was 20.3% versus 11.6%, clearly favoring the adjuvant therapy group. A recent review of the SEER database also reported an association between adjuvant chemoradiation therapy and improved survival in patients with locoregionally advanced disease.⁶¹ This finding prompted a multi center phase II trial of adjuvant capecitabine and gemcitabine followed by concurrent capecitabine and radiation therapy for patients with resected gallbladder cancer or extra hepatic cholangiocarcinoma. The results of this study were published in 2015 and showed promising findings of 65% two-year survival.⁶² These studies suggest that patients with gallbladder cancer with high risk for recurrence (T2 or greater, node-positive, or margin-positive) should be considered for adjuvant treatment with systemic chemotherapy or chemoradiation.

Table 63-4 Complications Postoperative Morbidity Following Resection of Gallbladder Cancer Over Time in the United States⁵⁶

Postoperative Morbidity	1991–1995 ($n = 681$)	1996–1999 ($n = 543$)	2000–2002 ($n = 833$)	2003–2005 ($n = 898$)	Total ($n = 2955$)

^aResults are reported as n (%).

Prognosis

The 5-year survival rate for all patients with gallbladder cancer is less than 5% in most series, with a median survival of 6 months. This is primarily because most patients present with unresectable disease. Of those patients undergoing resection, survival is dependent on depth of penetration and nodal status. Nearly 100% survival is reported after simple cholecystectomy for T1a disease, whereas patients with T2 and T3 tumors without nodal disease have a 5-year survival greater than 50%.^{14,15,40,52} Node positivity is an ominous finding, with few series reporting 5-year survivors.

Follow-up after Resection for Gallbladder Cancer

The most common sites of recurrence after resection of gallbladder cancer include carcinomatosis, intrahepatic metastases, or nodal recurrence in the retroperitoneum. For most tumors, local recurrence is found synchronously with diffuse intra-abdominal spread. Therefore, surgical treatment of recurrence has little potential for cure. The main goal of surgery after recurrence of resected gallbladder cancer is to provide palliation of symptoms such as pruritus or cholangitis associated with jaundice, or bowel obstruction associated with carcinomatosis. When jaundice or cholangitis is the presenting symptom of possible recurrence, a nonsurgical palliative approach using percutaneous transhepatic cholangiogram (PTC) and stenting is usually favored unless a benign postsurgical stricture is suspected. Because of the rapid growth of tumor in patients with recurrence, the hospitalization and recovery time from a surgical bypass is usually not justified for recurrences resulting in biliary obstruction.

The routine follow-up of a patient after resection of gallbladder cancer includes office visits every 3 months with physical examination and measurement of liver function tests, and cross-sectional imaging every 3 to 6 months for the first 2 years. In patients who remain free of disease at 2 years, follow-up should be continued on an individualized basis. Although CA19-9 may be elevated in patients with gallbladder cancer, the sensitivity and specificity are poor and, thus, should not be used for screening patients for recurrence.⁶³ If recurrence is identified, systemic therapy with gemcitabine and cisplatin should be considered as it has been shown to prolong survival in the setting of metastatic disease.⁶⁴ For patients who cannot tolerate this regimen, alternatives include single-agent gemcitabine or gemcitabine plus capecitabine.⁶⁵

Issues for the Future

Clearly, improving our ability to recognize early gallbladder cancer in high-risk geographic areas would have an important impact on outcome in these patients. This will likely require implementation of screening programs in high-risk areas, which could result in prophylactic cholecystectomy.⁶⁶

Additionally, standardization of minimum pathologic assessment of gallbladder specimens in high-risk areas is important to allow for accurate diagnosis, staging, and treatment of patients.

Further studies on characterization of molecular aberrations in gallbladder cancer by next generation sequencing and other technologies may lead to the discovery of targetable mutations and lead to the development of novel therapies. Additionally, there is a theoretical role for neoadjuvant therapy for patients with locoregionally advanced gallbladder cancer given their poor prognosis following surgery. Clinical trials in this area are needed.

BILE DUCT CARCINOMA

Bile duct carcinomas may arise within the liver (intrahepatic cholangiocarcinoma [ICC] or peripheral cholangiocarcinoma), at the liver hilum (hilar cholangiocarcinoma or Klatskin tumor), or in the extrahepatic bile duct (extrahepatic cholangiocarcinoma [ECC]). While all arise from the biliary epithelium, the location of these tumors affects prognosis as well as the potential for curative resection.

Resection of biliary neoplasms, particularly hilar cholangiocarcinoma, often requires radical resections and complex biliary reconstructions that should be performed only at high-volume, experienced centers. There is also a role for surgery in palliation for these cancers by providing biliary bypass for jaundiced patients with unresectable tumors. Because disease is often diagnosed late in the course and because complex operative techniques are required for potentially curative resection, these tumors represent one of the greatest challenges for definitive treatment. Adding to this is that there are no proven effective options for adjuvant therapy.

INCIDENCE

The incidence of ICC in the United States is approximately 0.7/100,000 with a similar mortality. During the last 30 years, it appears that both the incidence and mortality in the United States are increasing.⁶⁴ The overall incidence of hilar cholangiocarcinoma, the most common type, is 1.0/100,000 per year in the United States, although rates are higher in other geographic regions such as Israel and Japan.⁶⁸ Recent population studies have noted a trend toward a relative increased incidence of ICC compared to ECC.^{4,69,70} Using the Surveillance, Epidemiology and End Results-Medicare databases, Welzel et al.⁷⁰ noted HCV infection, chronic nonalcoholic liver disease and obesity, and smoking being associated only with ICC and not ECC, possibly explaining the divergent trends in incidence. Cholangiocarcinomas arise slightly more often in males, with a male-to-female ratio of 1.3:1 and an average age of 50 to 70 years.

Known risk factors for cholangiocarcinoma include primary sclerosing cholangitis, ulcerative colitis, choledochal cysts, and biliary tract infection, either with *Clonorchis* or in chronic typhoid carriers.⁷¹ Some industrial chemicals (e.g., nitrosamines, dioxin, asbestos, and polychlorinated biphenyls) have also been implicated in the pathogenesis of cholangiocarcinoma. Although there has been some suggestion of an increased risk of cholangiocarcinoma arising after transduodenal sphincteroplasty,⁷² it is difficult to determine if this is caused by the surgical intervention or the underlying disease leading to sphincteroplasty.

Pathology and Staging

More than 90% of these bile duct cancers are adenocarcinomas. They are morphologically described as nodular, which is the most common, scirrhous, diffusely infiltrating, or papillary. Histologic subtypes include acinar, ductular, trabecular, alveolar, and papillary. Papillary tumors have an improved outcome. Much less common types of bile duct tumors include cystadenocarcinomas, hemangioendotheliomas, and mucoepidermoid carcinomas.

STAGING

Table 63-5 American Joint Committee on Cancer, 7th Edition, Staging System for Perihilar Bile Duct Carcinoma

Stage	Tumor	Nodes	Metastasis
0	Tis	N0	M0
I	T1	N0	M0
II	T2a–b	N0	M0

In patients with ICC, negative prognostic signs include vascular invasion, multiple tumors, and lymph node metastases, but not tumor size.⁷³ These tumors can be sclerotic, masslike, or cystic lesions.

Historically, ECCs have been classified according to their location in the upper (60%), middle (15% to 20%), or lower third (15% to 20%) of the bile duct. Middle-third lesions arise between the cystic duct and the superior border of the duodenum. Lower-third lesions are found below the superior border of the duodenum but above the ampulla. The problem with this classification is that the anatomic landmarks are somewhat arbitrary and not clinically useful. Most mid–bile duct malignant obstructions are caused by gallbladder cancer. A more useful classification is to divide these lesions into upper-half or lower-half tumors, based on the location of the cystic duct as it enters the common duct (in the case of normal anatomy). The usefulness of this classification scheme is that it allows the surgeon to delineate whether a hepatic or pancreatic resection will be required for clearance of tumor. The AJCC TNM staging system (seventh edition) for bile duct cancers is described in [Tables 63-5](#) and [63-6](#).

Other staging systems have been created that attempt to incorporate clinically important indicators of resectability for hilar cholangiocarcinoma that are defined preoperatively, including hepatic lobe atrophy or portal vein involvement.⁷⁴ With the increasing acceptance of major hepatic resection for these tumors, this preoperative staging system attempts to define whether there is ipsilateral involvement alone, because tumors with bilateral extension past the primary biliary radicles are not resectable.

STAGING

Clinical Findings and Diagnosis

The presentation of patients with cholangiocarcinoma is variable. Patients with hilar or extrahepatic tumors most commonly present with painless jaundice. Symptoms of mild right upper quadrant pain, pruritus, anorexia, malaise, and weight loss may also be reported. Cholangitis is the presenting symptom in 10% to 30% of patients. Some patients, particularly those with ICC may be asymptomatic and have their tumors discovered incidentally or on evaluation for elevations of alkaline phosphatase and gamma-glutamyl transferase. Many of these patients will present to the surgeon with a biopsy showing adenocarcinoma without a known primary tumor. The standard evaluation in these patients should include tumor markers to rule out an elevated carcinoembryonic antigen (CEA) or α -fetoprotein (AFP); upper and lower endoscopy to evaluate for a gastrointestinal source; CT scan to assess for a primary tumor in the gastrointestinal tract or pancreas; and, in women, a mammogram. If no site of primary disease is found, in most patients, the diagnosis is ICC.

Various imaging tests are available to assess patients with cholangiocarcinoma. Abdominal ultrasound is noninvasive, easily available, and inexpensive, and thus is commonly used as a first imaging modality. It can establish the level of biliary obstruction and rule out other etiologies, such as choledocholithiasis. On CT, cholangiocarcinomas most often appear as hypodense masses with irregular margins on precontrast phase images, with peripheral rim enhancement on arterial phase, followed by progressive hyperattenuation on venous and delayed phases.⁷⁵ Intrahepatic lesions often exhibit associated capsular retraction and segmental/lobar atrophy and ductal dilatation. Hilar and proximal extrahepatic lesions demonstrate dilated intrahepatic biliary ducts with a normal, collapsed gallbladder, and, depending on the level of the tumor, a nondilated or partially dilated extrahepatic biliary tree (Fig. 63-5). While conventional CT is useful for assessment for extrahepatic, metastatic disease and perihilar adenopathy, high-resolution CT and/or MRI are required for accurate assessment of the tumor and for determination of respectability (Figs. 63-6 and 63-7).⁷⁵ Portal vein patency can be determined with ultrasound, CT, or MRI. Particularly for hilar tumors, signs of hepatic lobar atrophy should be carefully sought, because this indicates ipsilateral portal vein involvement by tumor. MRCP offers the potential of evaluating parenchymal, vascular, biliary, and nodal involvement with a single noninvasive examination.^{25,27,76}

In most centers, direct cholangiography is used to evaluate the extent of biliary involvement and provide palliation for jaundice. Endoscopic retrograde cholangiopancreatography (ERCP) has little role to play in high biliary obstruction because opacification of the proximal biliary tree is difficult. ERCP, however, can be effectively used to image more distal lesions. At the time cholangiography is performed, some authors advocate the routine preoperative placement of biliary drainage catheters to aid in intraoperative identification of the bile ducts.^{77,78} Others have found a higher incidence of infectious complications and mortality, and a longer hospital stay, after preoperative placement of biliary drainage catheters.⁷⁹⁻⁸¹ The difficulty in making the decision regarding preoperative stenting is that many patients are severely symptomatic because of jaundice and pruritus and require palliation, thus if the operation is delayed, many patients require palliation.

Figure 63-5. Computed tomography scan in a patient with hilar cholangiocarcinoma, demonstrating dilated intrahepatic ducts in the right lobe but inability to directly visualize tumor.

Figure 63-6. Coronal (A) and axial (B) magnetic resonance imaging in a patient with hilar cholangiocarcinoma. Dilated intrahepatic ducts are present with a soft tissue density consistent with tumor (arrows).

Figure 63-7. Coronal (A) magnetic resonance imaging and magnetic resonance cholangiopancreatography (B) in a patient with hilar cholangiocarcinoma, demonstrating dilated intrahepatic ducts narrowing at the area of obstruction.

In many cases, it is difficult to obtain pathologic confirmation of cholangiocarcinoma except in very advanced cases, even with the use of biliary brushings and cytology obtained at the time of direct cholangiography. In most cases, patients are offered surgical therapy based on clinical suspicion and radiographic appearance. In patients with ICC, cross-sectional imaging with CT scan is usually sufficient. Tumors may be masslike or may have cystic areas.

Surgery

Untreated, most patients with bile duct cancers die within a year of diagnosis.^{81,82} Surgical excision is the treatment of choice, with no other potentially curative therapy available. The immediate causes of death are most commonly hepatic failure or cholangitis related to tumor growth and inadequate drainage of the biliary tree.⁸³ Therefore, the goals of surgery are complete removal of tumor with R0 margins while leaving a sufficient liver remnant, and establishing adequate biliary drainage. Patients with ICC require additional consideration. Those patients with multifocal and especially bilobar intrahepatic tumors, even if technically resectable with negative margins and adequate remnant liver, should not be considered for resection. These patients have very poor prognosis indicating that bilobar hepatic spread represents hematogenous metastasis.⁸⁴ What remains controversial is whether peritumoral satellite lesions also represent metastatic disease. Because this is unknown and surgery is the only potentially curative therapy for these patients, satellite lesions are not currently considered a contraindication to resection.

Hilar cholangiocarcinoma is often unresectable due to local factors. These include invasion of the main portal vein or both the right and left portal veins and hepatic arteries and tumor extension into second-order biliary radicals of both right and left hepatic lobes. By contrast, tumors extending into second- or third-order biliary radicles on one side of the liver without vascular involvement can be resected for cure. It has become clear over the last three decades that curative treatment for patients with tumors of the hilum or those involving the upper half of the bile duct depends on aggressive excision that often requires a major liver resection. Until as recently as one decade ago, treatment of hilar cholangiocarcinomas was associated with mortality as high as 30%.^{85–89} Recently, major improvements in the safety of these operations have been demonstrated, and resection of hilar tumors now results in mortality of less than 10%, even when liver resections are required.^{85,86,88,90}

Role of Staging Laparoscopy

Because of the potential morbidity of a laparotomy that has no therapeutic benefit, staging laparoscopy has been advocated to save patients from unnecessary laparotomy. In patients with hilar cholangiocarcinoma, up to 25% will benefit from staging laparoscopy because of detection of occult extrahepatic disease.^{33,34} Laparoscopy is a very sensitive means to detect peritoneal metastases or additional intrahepatic disease through the use of laparoscopic ultrasound but is less sensitive in detecting nodal metastases or locally invasive tumors.

Partial Hepatectomy With or Without Bile Duct Resection

The extent of hepatectomy required for resection of cholangiocarcinoma is dependent on the tumor location in relation to the portal inflow and venous outflow of the liver. Intraoperative ultrasound is a useful adjunct for assessment of tumor extent and for small satellite lesions that may not be apparent on cross-sectional imaging.

Small ICCs may be removed by segmentectomy or sectorectomy, but these tumors are often large and require extended right or left hepatectomy. For hilar and proximal hepatic duct lesions, complete resection usually requires combined biliary and hepatic resection with or without major vascular reconstruction. Additionally, caudate resection is often required because of direct extension into caudate biliary radicles or parenchyma.^{74,89,91} Resection of the extrahepatic bile duct with Roux-en-Y hepaticojejunostomy to the remnant duct is required in these cases. Intraoperative assessment of the bile duct resection margin should be performed if additional duct can potentially be taken. If not, assessment on permanent sectioning is sufficient.

Lymphadenectomy

Regional lymphadenectomy is essential for accurate staging of cholangiocarcinoma, and may be important for locoregional disease control, but has historically been underperformed for intrahepatic and hilar tumors.^{73,92} Recent data have shown that lymph node metastases are present in 30% to 40% of patients.^{73,92–94} Regional lymph nodes include those along the porta hepatis, the hepatoduodenal

ligament, the hepatic artery for essentially all patients. In addition, for those with primary tumors of the right hemiliver, retropancreatic nodes should be removed. For those with primary tumors of the left hemiliver, perigastric lesser curve nodes (levels 1, 3, and 5) should be removed.⁹⁵ As is true for gallbladder cancer, there is currently no consensus on the minimum number of lymph nodes needed for accurate staging of cholangiocarcinoma.

Pancreaticoduodenectomy

For cholangiocarcinoma of the lower half of the extrahepatic bile duct, pancreaticoduodenectomy is requiring for complete tumor extirpation. The proximal bile duct margin should be assessed by frozen section to ensure tumor clearance. Regional lymphadenectomy is inherent in this procedure.

Liver Transplantation for Hilar CC and the Mayo Protocol

Orthotopic liver transplantation (OLT) was thought to hold promise for patients with hilar CC, because of the ability to achieve adequate margins by complete hepatectomy. Unfortunately, when used as a single treatment modality, results have been poor. Three- and 5-year survival rates have been reported at 25% to 30%.^{96–98} Because of this poor outcome, the Mayo Clinic developed a protocol combining neoadjuvant therapy with liver transplant, based on a strategy initially developed by the University of Nebraska. This protocol uses high-dose neoadjuvant 5-fluorouracil and brachytherapy followed by liver transplantation.^{99,100} Inclusion criteria include (i) locally advanced unresectable disease with either positive intraluminal brush cytology, positive intraluminal biopsy, or CA19-9 ≥ 100 in the setting of a radiographic malignant stricture; (ii) primary sclerosing cholangitis with resectable disease; and (iii) absence of medical contraindications for OLT. Since 2003, biliary aneuploidy as demonstrated by digital image analysis (DIA)(77) and fluorescent in situ hybridization have been considered equivalent to cytology.¹⁰¹ Exclusion criteria include (i) extrahepatic disease including regional lymph node involvement; (ii) uncontrolled infection; (iii) prior attempt at resection; (iv) prior treatment with radiation or chemotherapy; and (v) previous malignancy within 5 years. In this protocol, patients receive external beam radiotherapy to a target dose of 4,500 cGy with concomitant fluorouracil (5-FU). Following this, transcatheter iridium-192 brachytherapy with a target dose of 2,000 to 3,000 cGy is administered. Thereafter, patients receive oral capecitabine as tolerated until transplantation. It is important that, prior to transplantation, patients undergo a staging laparotomy, at which time biopsy of perihilar lymph nodes as well as any lymph nodes or nodules suspicious for tumor is performed. Only patients with negative staging operations remain eligible for transplantation.⁹⁹

Patients eligible for OLT under this protocol have locally advanced tumors but no pathologic nodal disease. The prolonged course of neoadjuvant therapy, staging laparotomy, and time on the OLT waiting list provides an opportunity to exclude patients demonstrating disease progression. This highly rigorous selection bias in favor of patients with biologically favorable disease is reflected in the early outcomes published from the Mayo group. In a recent review of 71 patients enrolled in this transplant

protocol, only 38 underwent transplantation (38%). These patients were compared to 26 patients (of 54 explored, 48%) who underwent successful resection. When compared to those undergoing resection (some with node-positive disease), patients undergoing transplantation were younger ($p < 0.001$) and more likely to have inflammatory bowel disease ($p < 0.03$) and PSC ($p < 0.001$). It is important that only 58% of patients had histologically proven cancer. In these highly disparate groups, 5-year survival was 82% after transplantation (38 patients) compared to 21% after resection of 26 patients ($p = 0.022$).⁹⁷ There were also fewer recurrences in the transplant patients (13% vs. 27%), and recurrences became apparent later after transplantation than after resection (mean 40 months vs. 21 months). Direct comparisons are difficult with this study given the differences between groups.

At present, OLT cannot be considered a standard form of therapy for hilar cholangiocarcinoma for patients with resectable disease, but it does offer a potential option for patients with underlying PSC or those with unresectable tumors who fit the rigorous inclusion and exclusion criteria of the protocol.

Prognosis After Resection

Results of major studies on resection of hilar cholangiocarcinoma are summarized in [Table 63-7](#). In patients amenable to curative resection, the median survival is 35 months with a 5-year survival rate of 10% to 30%.^{79,87,88,96,100,110} Surgical resection provides both improved survival and improved quality of life. The greatest risk factors for recurrence include the presence of positive margins, and node-positive tumors.¹¹¹

In patients with ICC, expected 3-year survival rates as high as 60% have been reported, with 5-year survival rates of 30% to 45%.^{35,111,112} Patients with unresectable disease have a median survival of 12 months.^{35,113} Thus, completely resected ICC appears to have an improved prognosis over proximal (hilar) cholangiocarcinoma. Patients with cholangiocarcinomas arising in the distal bile duct have both an increased resectability rate and improved prognosis over those with hilar cholangiocarcinomas.⁹⁰ Patients with resectable distal bile duct cancer have a 5-year survival rate of 30% to 50%, with a decreased survival if nodes are involved with tumor.^{114,115}

Unresectable Cholangiocarcinoma

6 For patients with unresectable hilar cholangiocarcinomas, significant improvement in quality of life can be achieved with surgical bypass. Palliative bypass can be performed in several ways. A partial excision of the left lateral segment and biliary-enteric anastomosis to the left hepatic duct (Longmire procedure) was used commonly in the past, but more recently surgical techniques have become less complicated and do not require hepatic parenchymal transection. One technique involves biliary decompression through the left duct, approached through the round ligament, a segment III bypass ([Fig. 63-8](#)). Opening the bridge of tissue just beneath the ligamentum teres allows access to the duct. In this position, a long anastomosis can be performed from the segment III duct to a jejunal limb because of the horizontal course of the duct in this location. Although less commonly used, the right hepatic duct can be approached at the base of the gallbladder fossa. This is technically more difficult and results in a higher rate of late bypass failure.¹¹⁶

Nonoperative palliative biliary decompression can be accomplished with percutaneous or endoscopic stenting, depending on the level of obstruction. Proximal lesions are usually approached percutaneously with placement of expandable stents or drainage catheters ([Fig. 63-9](#)). Internal stents result in fewer electrolyte abnormalities and improvement in patient comfort, although morbidity and mortality occurs in up to 30% of patients and stent occlusion is common.^{117–119} There is a significant risk of cholangitis with external and internal drainage, occurring in more than 90% of patients with metallic expandable internal stents in one series.¹¹⁸ Bleeding and bile leaks are also frequent complications. More recent techniques (e.g., photodynamic therapy) have been used to palliate patients with biliary obstruction and may hold some promise for the future.¹²⁰

Because patients with unresectable disease have a short median survival, those whose disease is clearly unresectable on preoperative imaging should undergo percutaneous internal or external drainage. In patients who undergo exploratory surgery and whose disease is found to be unresectable, surgical bypass offers fewer episodes of cholangitis, with an improved quality of life. In some series, surgical bypass for patients with unresectable disease is the only biliary drainage procedure ever required by the patient.

Figure 63-8. Surgical approach to segment III duct. **A:** The bridge of tissue present at the base of the liver is divided. **B:** The ligamentum teres is held superiorly to expose the tissue overlying the segment III duct. **C:** The segment III duct is exposed. **D:** The duct is opened in preparation for anastomosis with a Roux-en-Y jejunal limb. (Courtesy of Dr. L. H. Blumgart.)

In patients with unresectable distal cholangiocarcinomas, palliation can be achieved with surgical bypass, percutaneous biliary drains, or ERCP-placed stents. The simplest and most effective way to relieve jaundice is usually with an ERCP stent. Although surgical bypass offers improved patency and fewer episodes of cholangitis, the morbidity of the procedure is not warranted in patients with these aggressive tumors.

Adjuvant Therapy

To date, no chemotherapeutic regimen has consistently shown activity against cholangiocarcinoma. Many of the issues that pertain to chemotherapy trials in gallbladder cancer are directly relevant to the interpretation of trials for cholangiocarcinomas. Studies performed to date have typically been small, single-institution trials, including patients with both gallbladder and bile duct cancers.¹²¹

Although 5-fluorouracil (5-FU)-based chemotherapy is often offered to patients with unresectable disease, the likelihood of response is less than 10%. Capecitabine as a single agent may have some modest activity in cholangiocarcinomas.¹²² When capecitabine was used in combination with gemcitabine in a recent prospective study, overall survival was 14 months.⁶⁵ Gemcitabine and cisplatin combination therapy has also been tested in phase II studies of patients with advanced biliary tract carcinoma.^{123,124} Results of these studies demonstrated response rates of 27% to 34.5%, and overall survival of 9.7 to 11 months. The use of mitomycin C and doxorubicin (Adriamycin), in combination with 5-FU, has resulted in combined response rates of less than 30%, with higher toxicity than 5-FU alone.¹²⁵

With the exception of extrahepatic disease, there is no clear role for adjuvant chemotherapy in the treatment of cholangiocarcinoma. The previously mentioned phase II trial from 2015 showed a promising 2 year survival for patients with extra hepatic cholangiocarcinoma treated with adjuvant capecitabine/gemcitabine and concurrent capecitabine and radiation therapy.⁶² Aside from this study, however, previous data suggested no difference in overall survival (36% vs. 42%, $p = 0.6$) or loco regional recurrence (38% vs. 37%, $p = 0.13$) in patients who underwent R0 resection alone versus

those with high loco regional recurrence risk who received adjuvant chemoradiation therapy.¹²⁶ Similar to the recommendations for gallbladder cancer, patients with extra hepatic cholangiocarcinoma who undergo R0 or R1 resection should be considered for adjuvant capecitabine/gemcitabine and concurrent capecitabine and radiation therapy.

In cases of unresectable cholangiocarcinoma, the use of external beam radiation therapy has been explored.^{91,127–130} To date, no study has clearly demonstrated efficacy for this modality. Anecdotal reports of long-term survivors after external beam radiotherapy show that some individuals may benefit from such treatment, but this must be weighed against the potential complications (e.g., duodenal or bile duct stenosis and duodenitis). The most encouraging results involve use of intraoperative or interstitial radiation.^{127,128,130,131} Our current practice is to use combined interstitial radiation and external beam radiation in unresectable cases after palliative bypass. In patients whose disease is resected and have node- or margin-positive disease, systemic therapy with gemcitabine or 5-FU, or 5-FU-based chemoradiation, or enrollment in a clinical trial should be strongly encouraged.

Figure 63-9. A: Percutaneous transhepatic cholangiogram in a patient with hilar cholangiocarcinoma, demonstrating biliary obstruction at the confluence. The patient has previously had placement of internal/external stents for biliary drainage. B: Film demonstrates appearance of wall stents after deployment into the left and right biliary ducts. C: After stenting, the cholangiogram demonstrates adequate biliary drainage, with contrast filling the duodenum.

Follow-up After Resection of Cholangiocarcinoma

Recurrence following resection of ICC is within the liver in 60% of patients. While data are lacking, there is some evidence to suggest that there is a role for reresection in highly selected patients. The most likely site of recurrence after resection of hilar cholangiocarcinoma is locally within the bile duct, regional lymph nodes, or liver. Therapy for recurrence is palliative. Surgical reexcision is usually impossible because of the challenging anatomic location and the radical procedures that are required for resection of the primary tumor. The main symptoms of recurrence that demand palliation are pruritus or cholangitis associated with jaundice. For biliary drainage to relieve jaundice or cholangitis, either surgical drainage or drainage by PTC can be effective. Endoscopic drainage has little role in the relief of jaundice in patients who have had Roux-en-Y biliary reconstruction. For limited recurrences, intraluminal brachytherapy or external beam radiotherapy may improve palliation and, potentially, survival.¹³²

Routine follow-up consists of office visits every 3 months with physical examination and measurement of liver function tests. Although a rising alkaline phosphatase level is a reliable indicator of evolving biliary obstruction, patients recovering from liver resection and biliary obstruction can have persistent elevations of alkaline phosphatase. Up to 10% of patients with biliary surgical reconstruction, however, may develop a benign anastomotic stricture. Most patients with recurrence or a benign stricture will present with jaundice or cholangitis. Surveillance cross-sectional imaging is recommended every 3 to 6 months for the first 2 years following resection and should be individualized thereafter.

Issues for the Future

Further studies are needed to develop effective adjuvant, and potentially neoadjuvant, therapies for cholangiocarcinoma. Continued assessment of novel drugs and radiosensitizers, and biologic agents is warranted. A better understanding of the molecular pathogenesis and genetics of bile duct cancers may lead to new therapeutic strategies and possibly preventive strategies for high-risk populations.

BENIGN GALLBLADDER NEOPLASMS

Incidence

Benign tumors of the biliary tract are rare, but have been reported more frequently as imaging modalities (e.g., ultrasound and CT scan) have come into widespread and frequent use. In patients undergoing cholecystectomy, the reported incidence of benign gallbladder tumors is less than 3%.

Pathology

Polyps and Pseudotumors

Benign gallbladder tumors are most frequently polyps or polypoid lesions. The incidence of polyps in asymptomatic patients is about 5%.³ Cholesterol polyps (cholesterolosis), accounting for half of all gallbladder polypoid lesions, result from epithelium-covered, cholesterol-laden macrophages in the lamina propria.¹³³ These lesions are likely a result of an error in cholesterol metabolism. They extend from the mucosa on a narrow stalk, grossly appearing as yellow spots on the mucosal surface. Nearly all are multiple, and most are less than 10 mm in size.^{133,134} When a polyp is pedunculated, it is benign in most cases; alternatively, sessile “polyps” are more often malignant (Fig. 63-10). Inflammatory polyps result from chronic inflammation and extend by a narrow vascularized stalk into the gallbladder lumen. None of these lesions are considered premalignant, although isolated cases of cholesterolosis associated with in situ carcinoma have been reported.¹³⁵

Adenomas

Gallbladder adenomas are found infrequently. They may be tubular or papillary, both arising from the epithelial layer of the gallbladder. Multiple papillary adenomas, or papillomas, are called *papillomatosis*. A direct association between benign adenoma, adenoma containing carcinoma in situ, and invasive carcinoma has been demonstrated; thus these lesions are considered premalignant.¹³⁶ Malignant transformation, however, has only rarely been reported, primarily from large adenomas. In one series, all benign adenomas were less than 12 mm in diameter, whereas the adenomas with cancerous foci were greater than 12 mm.¹³⁵

Figure 63-10. T2-weighted magnetic resonance imaging scan showing a sessile polyp within the gallbladder (*arrow*) that was malignant on histologic examination.

Adenomyomatosis

Adenomyomatosis of the gallbladder is characterized by localized or diffuse hyperplastic extensions of the mucosa into, and often beyond, a hypertrophied gallbladder muscular layer. Hyperplasia occurs at outpouchings of the mucosa of the gallbladder through the wall (Rokitansky–Aschoff sinuses) and through the crypts of Luschka. This can result in focal thickening of the gallbladder wall, resembling gallbladder adenocarcinoma. The etiology is unknown. This lesion may be premalignant, because cases of adenocarcinoma arising in or near adenomyomatosis have been reported, but this relationship is unclear.^{127,138}

Other Benign Gallbladder Tumors

Other benign lesions include tumors arising from the tissue of the gallbladder wall, such as leiomyomas, lipomas, hemangiomas, granular cell tumors, and heterotopic tissue, including gastric, pancreatic, or intestinal epithelium.

Clinical Findings

Patients with benign gallbladder tumors typically present with symptoms consistent with choledocholithiasis, including right upper quadrant pain, fatty food intolerance, and nausea. Many benign gallbladder lesions are also discovered incidentally after elective cholecystectomy. Therefore, symptoms caused by benign lesions are difficult to separate from those caused by gallstones. Most lesions, however, are asymptomatic and are discovered incidentally during imaging for other abdominal conditions.

Diagnosis

Diagnosis of benign gallbladder polyps is usually made when an ultrasound study is obtained to evaluate a patient for symptoms consistent with gallstones. On ultrasound, a filling defect that does not change with position is likely a polyp or carcinoma and not a gallstone. Cholesterol polyps are typically small, submucosal, multiple, and hyperechoic on ultrasound because of their high cholesterol content. Other than this typical appearance and the fact that malignant polyps are usually more than 1 cm in size, it is difficult to differentiate benign from malignant polyps.

Both intravenous contrast-enhanced and unenhanced CT may be important in distinguishing benign from malignant polyps. In a recent series examining 31 polypoid lesions of the gallbladder, contrast-enhanced CT detected all of the lesions. Benign polyps were not visualized with unenhanced CT, unlike neoplastic tumors, thus improving the ability to distinguish these lesions when both enhanced and unenhanced CT scans were obtained.⁹ Endoscopic ultrasound has also been used to image these lesions, and may be more accurate than transabdominal ultrasound in differentiating benign from malignant tumors.²²

Treatment

Large polyps, greater than 10 mm, have the greatest malignant potential.^{9,133,134} Without the evidence of invasion or metastatic disease, however, no radiologic test can reliably differentiate benign from

malignant lesions. Therefore, if large (>1 cm) polyps are present, even in asymptomatic patients without stones, cholecystectomy is warranted.¹³⁹ Additionally, resection is recommended for smaller pedunculated lesions with evidence of a vascularized stalk. Small pedunculated lesions with the gross characteristics of a benign cholesterol polyp may be observed and resected only if symptomatic. Although these lesions have routinely been followed with ultrasound, a recent prospective study suggested that polyps smaller than 1 cm do not progress to carcinoma.¹⁴⁰ Cholecystectomy, however, is still considered the standard of care if there is any increase in size.

BENIGN BILE DUCT NEOPLASMS

Incidence

Benign bile duct tumors, at times clinically resembling hilar cholangiocarcinoma, are less common, occurring in less than 1% of patients.⁴

Pathology

Attesting to the rarity of these lesions, only two cases of benign extrahepatic bile duct disease occurred in 4,200 biliary tract operations in one institution.¹⁴¹ The most common benign tumors of the extrahepatic biliary tree arise from the glandular epithelium lining the ducts; about two-thirds of benign tumors are polyps, adenomatous papilloma, or bile duct adenomas. Most are found in the perampullary region, but they can be distributed throughout the entire biliary tree (Fig. 63-11). Multiple papillomas also have been reported throughout the intrahepatic and extrahepatic biliary tree, termed *multiple biliary papillomatosis*. Although local recurrence and progression to death from obstructive jaundice and cholangitis occur frequently in these rare cases, these tumors have little, if any, malignant potential. Other benign tumors (e.g., cystadenoma, granular cell myoblastoma, leiomyoma, and heterotopic tissue) have also been reported.

One condition that deserves consideration is the case of “malignant masquerade,” an inflammatory, fibrotic lesion clinically resembling hilar cholangiocarcinoma, but pathologically consisting only of extensive fibrosis and inflammatory cells without evidence of dysplasia or preneoplastic change.¹⁴²⁻¹⁴⁴ In patients being considered for palliative treatment alone with presumed hilar cholangiocarcinoma, it is essential to obtain a tissue diagnosis. It is inappropriate to treat benign lesions by percutaneous stenting because of the excellent outcome after resection of these lesions.

Clinical Findings

Biliary obstruction, with resultant jaundice or cholangitis, is frequently the presenting symptom in patients with benign bile duct tumors. Symptoms may also include epigastric pain or nausea. Because these tumors are indolent, symptoms may be intermittent or gradually progressive.

Figure 63-11. Distribution of papillomas and adenomas of the biliary tree. The ampulla and common bile duct are the most frequent sites.

Diagnosis

Because of the presence of jaundice, benign bile duct tumors are usually initially evaluated with ultrasound. Many patients then undergo ERCP or PTC and CT scan. A diagnosis of malignant masquerade should be suspected in patients with mass lesions that resemble hilar cholangiocarcinomas, but without lobar atrophy or portal vein involvement.

Treatment

Resection and reconstruction are performed to relieve jaundice and cholangitis. The preferred reconstruction is a Roux-en-Y choledochojejunostomy to decrease the risk of postoperative biliary stricture or recurrent cholangitis.

SECTION I: COLON AND RECTUM

Chapter 64

Colon and Rectal Anatomy and Physiology

Sandy H. Fang and Elizabeth C. Wick

Key Points

- 1 The mesorectum is invested by the fascia propria of the rectum.
 - 2 The ileocolic branch of the superior mesenteric artery supplies the right colon and part of the transverse colon.
 - 3 The inferior mesenteric artery supplies part of the transverse colon, sigmoid colon, and rectum.
 - 4 The inguinal lymph nodes drain the lymphatics from the anal canal below the dentate line.
 - 5 The colon has 10^{13} bacteria, which promote mucosal immunity, help digest complex nutrients, and protect against pathogenic organisms.
 - 6 Alterations in the colonic flora have been associated with inflammatory bowel disease and colorectal cancer.
 - 7 Constipation is one of the most common conditions treated by physicians, but only rarely is it due to colonic inertia.
 - 8 During postoperative ileus, the stomach recovers after 1 to 2 days, the small bowel after 1 day, and the colon after 3 days.
 - 9 Thoracic epidural use after colorectal surgery can shorten postoperative ileus.
 - 10 Sacral nerve stimulation is a newer and effective treatment for fecal incontinence.
-

INTRODUCTION

While the complex coordination of stool through the colon, rectum, and anus is the main function of the colon, it also plays a role in the complex digestion and absorption of carbohydrate and protein residue, creates a balanced environment for bacteria, and lubricates stool for transit. Understanding the anatomy and physiology of the colon, rectum, and anus is important to treating the pathology associated with it.

EMBRYOLOGY OF THE COLON AND RECTUM

The primitive gut is derived from endoderm and begins to form during the third to fourth week of gestation. It is divided into three segments: foregut, midgut, and hindgut. Embryologically, the colon is derived from the midgut, which is supplied by the superior mesenteric artery, and the hindgut, which is supplied by the inferior mesenteric artery.¹ The midgut gives rise to the small intestine distal to the ampulla of Vater, the cecum and appendix, the ascending colon, and the right half to two-thirds of the transverse colon. During the sixth gestational week, the midgut herniates from the abdominal cavity into the extraembryonic coelom, undergoes a 270-degree counterclockwise rotation around the superior mesenteric artery, and then returns to the abdominal cavity at 10 weeks' gestation. The hindgut gives rise to the distal one-third of the transverse colon, descending and sigmoid colon, rectum, and upper portion of the anal canal. The terminal end of the hindgut is the endoderm-lined pouch termed the *cloaca*. During development, the cloaca is partitioned by the urorectal septum into the rectum and upper anal canal and urogenital sinus. Ultimately, the distal anal canal arises from canalization of the ectoderm. The pectineal or dentate line marks the junction between tissue derived from endoderm and ectoderm in the anal canal.

ANATOMY OF THE COLON AND RECTUM

The colon begins in the right lower quadrant of the abdomen as the cecum. The ileum enters the colon at the posteromedial aspect at the ileocecal valve.¹ Characteristics unique to the colon are (a) taeniae coli, (b) haustra, and (c) appendices epiploicae, located on the antimesenteric surface of the colon. There are three taeniae (anterior, posterior medial, and posterior lateral), which are condensations of the outer longitudinal muscle layer in the colon. They are named according to their attachments: taenia mesocolica (attached to the mesocolon), taenia omentalis (attached to the greater omentum), taenia libera (no attachments). The taeniae originate at the base of the appendix, course along the length of the colon, and then converge at the rectosigmoid junction.

On average, the colon is 150 cm long. The taenia are one-sixth shorter than the colon and are believed to be responsible for pockets of the colon wall called sacculations or haustra.¹ The epiploicae appendices are fat appendages seen on the colonic serosa.

The colon consists of five layers: mucosa, submucosa, circular muscle layer, longitudinal muscle layer, and serosa (Fig. 64-1). Microscopically, the colonic mucosa is a columnar epithelium marked by crypts and goblet cells. Unlike the small intestine, the columnar epithelium of the colon and rectum does not have villi. The submucosa is the strongest layer of bowel and contains Meissner plexus. The myenteric plexus of Auerbach is on the external surface of the circular muscle layer. The outer longitudinal muscles form the taeniae coli. Finally the serosa is not present in the lower portions of the rectum.

The colon begins in the right lower quadrant with the cecum. The cecum extends approximately 6 to 8 cm below the ileocecal valve (where the terminal ileum enters the posteromedial aspect of the cecum) (Fig. 64-2). The angulation between the ileum and cecum via the superior and inferior ileocecal ligaments is important in maintaining competence against reflux at the ileocecal junction.² The cecum is the widest portion of the colon (7.5 to 8.5 cm in diameter), has the thinnest wall, and is entirely enveloped by peritoneum. The appendix originates from the lowest portion of the cecum and can be readily identified by following the converging taeniae. In 85% to 95% of people, the appendix lies posterior to the cecum, lateral and in line to the terminal ileum, but the position can vary, with the most frequent variants being retrocecal (toward the psoas muscle), pelvic, and retroileal.³ During colonoscopy, visualization of the appendiceal orifice and ileocecal valve are the landmarks required in a complete colonic examination. From the cecum, the right colon ascends to the hepatic flexure (approximately 15 cm). The hepatic flexure is anterior to the inferior pole of the right kidney and overlies the second portion of the duodenum. The hepatic flexure is marked by medial, anterior, and downward angulation of the colon. When the right colon and mesentery are mobilized during a colectomy, care must be taken to avoid injury to the underlying duodenum. Only the anterior surface of the right colon is invested with peritoneum; laterally, the white line of Toldt marks the extent of the peritoneal covering and serves as an important landmark during surgical mobilization of the colon.

Figure 64-1. Layers of the colonic wall.

The transverse colon stretches from the hepatic flexure to the splenic flexure and is the longest segment of colon (between 30 cm and 60 cm). The transverse colon is suspended by the transverse mesocolon and is completely intraperitoneal. It is the most mobile portion of the colon and may descend

to the level of the iliac crests or deep into the pelvis. The greater omentum descends from the greater curve of the stomach in front of the transverse colon and then ascends to attach to the transverse colon on its anterosuperior edge. To mobilize the transverse colon or enter the lesser sac, the fusion plane of the omentum to the transverse colon must be dissected. The splenic flexure is situated high in the left upper quadrant, more cephalad than the hepatic flexure, and lies anterior to the mid-left kidney and abuts the lower pole of the spleen. There are attachments from the colon to the diaphragm at the level of the 10th and 11th ribs and spleen (phrenocolic and splenocolic ligaments), and these must be carefully divided during mobilization of the splenic flexure to avoid splenic injury.

The descending colon is approximately 25 cm long and courses from the splenic flexure to its junction with the sigmoid colon at the pelvic brim. It lies anterior to the left kidney and, like the right colon, the anterior, lateral, and medial portions of the descending colon are covered by peritoneum.

The sigmoid colon extends from the pelvic brim to the sacral promontory, where it continues as the rectum and generally measures 15 to 50 cm in length. It is completely invested by peritoneum. The rectosigmoid junction is marked by the convergence of the colonic taenia. The sigmoid colon is extremely mobile and has a generous mesentery that extends along the pelvic brim from the iliac fossa across the sacroiliac joint to the second or third sacral segment. Because of its mobile mesentery, the sigmoid colon can twist and cause an obstruction, termed *sigmoid volvulus*. The left ureter runs in the intersigmoid fossa, which is at the base of the mesosigmoid. When a high ligation of the inferior mesenteric artery is performed during a cancer operation or the sigmoid colon is being mobilized along the white line of Toldt, the left ureter should be identified to avoid inadvertent injury. Preoperative placement of urinary stents can be useful for locating the ureter intraoperatively in complex, reoperative pelvic surgery.

1 At the sacral promontory, the colon becomes the rectum. The outer layer of the rectal wall is composed of the longitudinal muscle, where the three teniae splay. The rectum measures 12 to 15 cm in length. It proceeds posterior and caudal along the curvature of the sacrum and coccyx, passing through the levator ani muscles, at which point it turns abruptly caudal and posteriorly at the anorectal ring, becoming the anal canal. Anterior to the rectum are the uterine cervix and posterior vaginal wall in women, and the bladder and prostate in men. Posteriorly, the rectum occupies the sacral concavity where the median sacral vessels, presacral veins, and sacral nerves run, all of which are invested in the presacral fascia. The rectum is marked by three curves. The upper and lower curves are convex and to the right, while the middle is convex and to the left. Within the lumen, these correspond to the valves of Houston, which separate the lower third, middle third, and upper third of the rectum – important landmarks when the location of a rectal abnormality is established endoscopically (the lower rectal valve is at 7 to 8 cm from the anal verge, middle rectal valve at 9 to 11 cm, and upper rectal valve at 12 to 13 cm).⁴ The valves do not contain all layers of the bowel wall and thus biopsy at this location carries minimal risk of perforation. The middle valve of Houston is the internal landmark corresponding to the anterior peritoneal reflection. The anterior and lateral surfaces of the upper third of the rectum are intraperitoneal, whereas only the anterior surface of the middle third of the rectum is intraperitoneal in location. The lower third of the rectum is entirely extraperitoneal. The mesorectum is the term used to describe the areolar tissue surrounding the rectum that contains nerves, lymphatics, and terminal branches of the superior hemorrhoidal branch of the inferior mesenteric artery. Although it invests the rectum circumferentially, the mesorectum is most prominent posterior to the rectum. It is invested by the fascia propria of the rectum, a continuation of the parietal endopelvic fascia (Fig. 64-3). The fascia propria (investing fascia) includes the distal two-thirds of the posterior rectum and the distal one-third of the anterior rectum, where it is no longer intraperitoneal. A total mesorectal excision entails removal of the entire rectum without violating the fascia propria of the rectum. This is accomplished by mobilizing the rectum using the plane between the fascia propria of the rectum and the presacral fascia. Anterior to the investing fascia (fascia propria) is a delicate layer of connective tissue known as Denonvilliers fascia, which separates the rectum from its anterior structures. Waldeyer fascia (rectosacral fascia) is the presacral fascia that is an extension of the parietal pelvic fascia from the periosteum of sacral segment four to the posterior wall of the rectum. It contains branches of the sacral splanchnic nerves. Below Waldeyer fascia is the supralelevator or retrorectal space.

Figure 64-2. General anatomic components of the colon.

Figure 64-3. Fascial relationships of the pelvis.

The surgical anal canal begins at the anorectal ring or levator ani muscles and extends to the anal verge. It measures 2 to 4 cm and is usually longer in men than in women. The internal anal sphincter (continuation of the circular smooth muscle of the rectum) and the external anal sphincter (continuation of the puborectalis muscle) encircle the anal canal and control fecal continence. The internal anal sphincter relies on autonomic innervation, while the external anal sphincter uses somatic innervation. The median length and thickness of the female anterior external sphincter is 11 and 13 mm and thus a small tear sustained during vaginal delivery may cause fecal incontinence.⁵ There are three layers of the external sphincter – subcutaneous (traversed by the conjoined longitudinal muscle with some fiber attachments to the skin), superficial (connective tissue attaches posteriorly, forming the anococcygeal ligament), and deep (continues with the puborectalis muscle). Between the internal and external anal sphincters, the longitudinal muscle of the rectum joins fibers of the levator ani and puborectalis muscles to form the conjoined longitudinal muscle. The dentate line marks the transition between the columnar epithelium of the intestine and the squamous epithelium of the anal canal. The transition between these two epithelia is called the anal transitional zone. The Columns of Morgagni are the 6 to 14 longitudinal folds located at the dentate line. Small pockets between these columns called anal crypts contain anal glands, which may become obstructed with foreign material to cause an infection. Below the dentate line is the anoderm, which extends to the anal verge and does not contain accessory skin structures, such as hair, sebaceous and sweat glands. The autonomic nervous system innervates proximal to the dentate line and the somatic nervous system supplies the anoderm and distally.

Pelvic Floor

The perineal body is the tendinous insertion of the external anal sphincter, bulbocavernosus, and superficial and deep transverse perineal muscles. It supports the perineum and separates the vagina

from the anus.

Three striated muscles that attach to the pubic bone make up the pelvic floor or levator ani muscles: iliococcygeus, pubococcygeus, and puborectalis. The pelvic floor muscles are supplied by branches from the third sacral nerve, while the external anal sphincter is supplied by nerve fibers traveling with the pudendal nerve on the levators undersurface.

The puborectalis originates from the back of the symphysis pubis and forms a U-shaped sling as it joins the opposite muscle posteriorly. The iliococcygeus muscle arises from the ischial spine and posterior part of the obturator fascia and travels inferiorly, posteriorly, and medially to insert into the last two segments for the sacrum and coccyx. The pubococcygeus muscle arises from the anterior half of the obturator fascia and the posterior pubis. Its fibers are directed backward, downward, and medially, where they decussate with fibers of the opposite side. The decussation is called the anococcygeal raphe.

Anorectal Spaces

The perianal space surrounds the anal canal superficially and contains the external hemorrhoidal plexus. The ischioanal space extends laterally and goes superiorly to the levator ani from the skin on the perineum. The levator ani and external sphincter muscles form the medial boundary, while the lateral wall is formed by the obturator fascia. The superficial postanal space connects the perianal spaces with each other posteriorly below the anococcygeal ligament, while the deep postanal space lies above the anococcygeal ligament. The ischioanal and perianal spaces make the ischioanal fossa. The deep postanal and ischioanal spaces form a horseshoe configuration that may be involved in a horseshoe abscess. Below the perianal space between the sphincter muscles is the intersphincteric space. The submucosal space contains the internal hemorrhoidal plexus and lies between the internal anal sphincter and the mucosa distal to the dentate line. Proximally, it becomes the submucosa of the rectum. Above the levator complex is the supralelevator space, which extends superiorly to the peritoneum at the rectosacral fascia. The retrorectal space extends above the rectosacral fascia and lies between the upper two-thirds of the rectum and sacrum.

Arterial Blood Supply

2 3 The arterial blood supply to the colon, rectum, and anus is highly variable. The following summarizes the general courses of the arterial blood supply. The superior mesenteric artery arises from the aorta, runs posterior to the pancreas, and passes anterior to the third portion of the duodenum (Fig. 64-4). In addition to supplying the small bowel through jejunal and ileal branches, the superior mesenteric artery gives rise to the ileocolic, right colic, and middle colic branches that supply the cecum, ascending colon, and proximal transverse colon. The right colic arterial anatomy is particularly variable and can be absent or arise from the ileocolic or the superior mesenteric artery. The middle colic artery has a right branch that supplies the hepatic flexure and the right portion of the transverse colon, while the left branch supplies the left portion of the transverse colon. The inferior mesenteric artery arises from the anterior surface of the aorta, typically 3 to 4 cm above the aortic bifurcation, and supplies the distal transverse colon, descending colon, sigmoid colon, and upper rectum. The inferior mesenteric artery gives rise to the left colic artery and sigmoidal branches, then continues in the sigmoid mesentery, and after crossing the left iliac vessels, is renamed the superior rectal/hemorrhoidal artery. The inferior mesenteric artery may also function as an important collateral vessel to the lower extremities during instances of distal aortic occlusion. The superior hemorrhoidal artery descends behind the rectum and splits into right and left branches in the mesorectum. It is the main blood supply of the rectum. The middle and inferior rectal/hemorrhoidal arteries arise from either the internal pudendal arteries or the hypogastric arteries and supply the distal two-thirds of the rectum. The presence of the middle rectal artery, in particular, can be variable. A series of arterial arcades along the mesenteric border of the entire colon, known as the *marginal artery of Drummond*, connect the superior mesenteric and inferior mesenteric arterial systems. The marginal artery may be attenuated or absent at the distal transverse colon/splenic flexure, the delineation between the midgut and hindgut, and thus ischemic colitis most commonly affects this region. The *arc of Riolan* (“meandering mesenteric artery”) is a short loop connecting the left branch of the middle colic artery and the trunk of the inferior mesenteric artery. The inferior rectal/hemorrhoidal arteries traverse the ischioanal fossa and supply the anal canal and external anal sphincter muscles.

Figure 64-4. Arterial blood supply of the colon.

Figure 64-5. Venous drainage of the colon by the portal vein.

VENOUS DRAINAGE

The veins that drain the large intestine bear the same terminology and follow a course similar to that of their corresponding arteries (Fig. 64-5). The veins from the right colon and transverse colon, along with the veins draining the small intestine, drain into the superior mesenteric vein. The superior mesenteric vein runs slightly anterior to and to the right of the superior mesenteric artery. The superior mesenteric vein courses beneath the neck of the pancreas, where it joins with the splenic vein to form the portal vein. The inferior mesenteric vein is a continuation of the superior rectal vein and drains blood from the

left colon, sigmoid colon, rectum, and superior anal canal. The inferior mesenteric vein follows a course of its own, starting at the left colic artery, and ascends over the psoas muscle in a retroperitoneal plane. The vein courses under the body of the pancreas to drain into the splenic vein. During an anterior resection of the rectum, division of the inferior mesenteric vein at the inferior border of the pancreas can provide additional mobility of the left colon to facilitate a coloanal anastomosis. The superior hemorrhoidal (rectal) veins drain blood from the rectum and upper part of the anal canal, where the internal hemorrhoidal plexus is situated, into the portal system via the inferior mesenteric vein. The middle hemorrhoidal (rectal) veins drain the lower part of the rectum and upper part of the anal canal into the systemic circulation via the internal iliac veins. The inferior hemorrhoidal (rectal) veins drain blood from the lower rectum and anal canal, where the external hemorrhoidal plexus is located, via the internal pudendal veins into the systemic venous circulation via the internal iliac veins. In the setting of portal hypertension, the superior, middle, and inferior hemorrhoidal veins interact to shunt venous blood from the portal system into the systemic circulation.

LYMPHATIC DRAINAGE

4 Lymphatic drainage generally follows the arterial blood supply of the colon and rectum. In the anal canal, lesions above the dentate line drain into the inferior mesenteric lymph nodes. Lesions below the dentate line drain into the internal iliac lymph nodes but can also drain into the inferior mesenteric lymph nodes.

Neural Components

The colon possesses extrinsic and intrinsic (enteric) neuronal systems. The extrinsic system consists of sympathetic and parasympathetic nerves that inhibit or stimulate colonic peristalsis, respectively. The sympathetic innervation to the right colon originates from the lower thoracic segments of the spinal cord and travels in the thoracic splanchnic nerves to the celiac and superior mesenteric plexuses. Postganglionic fibers emerge from here and course along the superior mesenteric artery and its branches to the right side of the colon. The parasympathetic nerves originate from the right vagus nerve and travel along with the sympathetic nerves to the right side of the colon. The left side of the colon and the rectum receive sympathetic fibers that arise from L1 through L3 segments of the spinal cord. This passes through the ganglionated sympathetic chains and leaves as a lumbar sympathetic nerve to join the preaortic plexus. It extends along the inferior mesenteric artery as the mesenteric plexus and then becomes the presacral nerve or superior hypogastric plexus. These hypogastric nerves are identified at the sacral promontory 1 cm lateral to the midline. The key zones of sympathetic nerve damage are during ligation of the inferior mesenteric artery and during initial posterior rectal mobilization adjacent to the hypogastric nerves. The parasympathetic supply to the left side of the colon and the rectum comes from S2 through S4 spinal cord segments. The sacral nerve fibers become the *nervi erigentes*, which join the pelvic plexus at the pelvic side walls. To prevent injury during full mobilization of the rectum, the lateral ligament should be cut close to the rectal side wall. Both the sympathetic and parasympathetic nervous systems play a role in erection, in that damage to the parasympathetics can lead to erectile dysfunction, while retrograde ejaculation can occur with damage to sympathetic nerve injury.

The intrinsic, or enteric, nervous system consists of two groups of plexuses that are identified by their location within the colon wall. This system can function independently of the central nervous system and controls motility and exocrine and endocrine functions of the gut, and is involved in intestinal immune regulation and inflammatory responses. The Meissner plexus is located in the submucosa between the muscularis mucosae and the circular muscle of the muscularis propria and is important in secretory control. The myenteric plexus, also known as the *Auerbach plexus*, is located between the inner circular muscle and outer longitudinal muscle layers of the colon and primarily controls intestinal motility.⁴

The internal anal sphincter is supplied by the sympathetic and parasympathetic nerves that supply the lower rectum. The parasympathetic nerves are inhibitory. The external sphincter is supplied by the inferior rectal branch of the internal pudendal nerve and the perineal branch of S4. Sensation of the anal canal is from the inferior rectal nerve, a branch of the pudendal nerve.

PHYSIOLOGY

The colon's function is to absorb, store, digest carbohydrate and protein residues, and secrete mucus.

Absorption

The colon absorbs water, sodium, and chloride and secretes potassium and bicarbonate. The physiologic control of colonic water and electrolyte transport requires careful integration of neural, endocrine, and paracrine components. Although colonic epithelium does not actively absorb glucose or amino acids as the small-intestinal epithelium does, the colon does absorb short-chain fatty acids and vitamins that are produced by bacterial breakdown of nonabsorbed carbohydrates and amino acids. These short-chain fatty acids, which include acetate, butyrate, and propionate, are absorbed in a concentration-dependent fashion. They are a major (70% of colonic mucosal energy) energy substrate for colonic epithelial cells and represent the major fecal anions.⁶

Approximately 1,500 mL of ileal effluent reaches the cecum in a 24-hour period, 90% of which is reabsorbed in the colon; 100 to 150 mL of water remains in stool. The colon has a tremendous capacity that allows it to absorb as much as 5 to 6 L of water within a 24-hour period. When colonic capacity is exceeded, diarrhea results.⁷ Normally formed feces consist of 70% water and 30% solid material. Almost half of the solid material is made up of bacteria and the other half is composed of undigested food material and desquamated epithelium. Water absorption in the colon is a passive process that depends primarily on the osmotic gradient established by the active transport of sodium across the colonic epithelium. The composition of ileal effluent and luminal flow rates also play an important role in water absorption. Upsetting the balance of these three factors results in diarrhea. The absorptive capacity is not the same throughout each segment of the colon. Salt and water absorption is greatest in the right colon. Patients undergoing a right hemicolectomy should therefore be counseled preoperatively that they may experience loose bowel movements in the early postoperative period. Patients should also be reassured that this will resolve with time as the remaining colon adapts.

Sodium absorption by the colonic epithelium is an active cellular transport process similar to that seen in small-intestinal and renal epithelial cells.⁸ Initially, sodium absorption involves the passive movement of sodium across the apical membrane into the mucosal cell down an electrochemical gradient. To maintain an adequate electrochemical gradient, intracellular sodium is removed from the cell into the interstitial space in exchange for potassium at the basolateral membrane. This is an energy-dependent process that is controlled by $\text{Na}^+\text{-K}^+$ -adenosine triphosphatase (ATPase). Mineralocorticoids (predominantly aldosterone) and glucocorticoids accelerate sodium absorption and potassium excretion in the colon by increasing $\text{Na}^+\text{-K}^+$ -ATPase activity.⁹ Potassium movement into the colonic lumen is primarily a passive process that depends on the electrochemical gradient generated by the active transport of sodium across colonic epithelial cells. Chloride absorption in the colon is generally thought to be an energy-independent process that is associated with reciprocal exchange for bicarbonate at the luminal border of the mucosal cell.¹⁰ Patients with a ureterosigmoidostomy may develop hyperchloremia and secrete excessive amounts of bicarbonate.

Twenty percent of urea synthesized by the liver is metabolized mainly in the colon. This is converted into 200 to 300 mL of ammonia each day, of which most is absorbed by passive coupled diffusion with bicarbonate and forms ammonia and carbon dioxide. Ammonia is also derived from dietary nitrogen, epithelial cells, and bacterial debris. Mucus is produced by goblet cells and secreted into the lumen via stimulation of the pelvic nerves.

Colonic Flora

5 The bacterial flora of the colon is established soon after birth and depends in large part on dietary and environmental factors. The colon is populated by approximately 10^{13} commensal bacteria.¹⁰ The vast majority of the normal colonic flora consists of anaerobic bacteria, with *Bacteroides* species being most prevalent, particularly *B. fragilis*.¹¹ Aerobic colonic bacteria are mainly coliforms and enterococci, with *Escherichia coli* being the most predominant coliform. The colonic flora is important for (a) digestion and absorption of complex macromolecules, (b) protecting the colon against invasion by noncommensal bacteria, and (c) development of mucosal immunity. Fermentation of carbohydrates generates short-chain fatty acids, including acetic acid, propionic acid, and butyrate, which is the primary nutrient for the colonic mucosa. Colonic bacteria also produce certain vitamins, such as vitamin K and B_{12} , which are absorbed by the host. The enterohepatic circulation of bilirubin and bile acids depends on bacterial enzymes produced by fecal flora. The degradation of bile pigments by colonic bacteria gives stool its

characteristic brown color. Colonic bacteria also play an important role in preventing infection by controlling the growth of potentially pathogenic bacteria such as *Clostridium difficile*.

6 Host and colonic flora have a mutualistic relationship; however, disturbances of this coexistence can lead to human disease.¹² Changes in diet and use of antibiotics can dramatically alter the microbiome. Dysregulation of the flora has been implicated in the pathogenesis of inflammatory bowel disease, obesity and, to a lesser extent, colorectal cancer. Increasingly, dysregulation has also been linked to nongastrointestinal diseases including autism and other neurologic conditions. In animal studies, mice with certain immune deficiencies that make them prone to colitis fail to develop colitis when raised under germ-free conditions. Analysis of the microbiota of patients with inflammatory bowel disease revealed markedly different flora compositions in ulcerative colitis, Crohn disease, and healthy control patients. Similarly, certain genetically altered mice with a propensity to develop colorectal cancer fail to develop tumors in germ-free conditions. Although studies of human flora and colorectal cancer are limited, preliminary studies have raised interest in modulating the colonic flora as a way to treat and/or prevent colitis and other diseases of the colon.

Colonic Motility

Motor activity varies greatly throughout the colon. There are two patterns of colonic motility: segmental contractions, which are single or clustered contractions, and propagated activity, which is either high-amplitude (>100 mm Hg) propagated contractions (HAPCs) or low-amplitude (<60 mm Hg) propagated contractions (LAPCs). *Segmental contractions* are intermittent contractions of the longitudinal and circular muscles that result in the segmented appearance of the colon.¹³ These contractions propel luminal contents in a back-and-forth pattern over short distances, slowing aboral transit and allowing for water reabsorption.¹⁴ *Propagated activity* consists of strong, propulsive contractions of the smooth muscle that involve a long segment of colon.¹⁵ The LAPCs move luminal contents forward at a rate of 0.5 to 1.0 cm/s and typically last for 20 to 30 seconds.¹³ HAPCs occur three to four times per day, primarily after awakening, exercise, and after meals.

The orderly progression of colonic luminal contents from cecum to anus requires the coordination of smooth muscle contractions. Calcium-dependent cyclic depolarization and repolarization of the colonic smooth muscle cell membrane generates a basic electrical pattern of slow-wave activity. This activity allows each smooth muscle cell to control its own contraction and to couple with adjacent smooth muscle cells.¹⁶ The extrinsic (autonomic) and intrinsic (enteric) neuronal systems also interact to influence colonic motility.

Defecation

As the fecal mass enters the rectum, the internal anal sphincter relaxes, while the external anal sphincter contracts to maintain continence. Distention of the rectum in this setting is the primary stimulus for defecation to begin. At this point, the urge to defecate may be suppressed by conscious contraction of the external anal sphincter. Receptive relaxation of the rectal ampulla accommodates the fecal mass and the urge to defecate passes unless the volume of feces is extremely large or the sphincter mechanism is impaired. If the subject voluntarily accedes to the urge to defecate, a Valsalva maneuver occurs, which increases the intra-abdominal pressure to overcome the resistance of the external anal sphincter. Relaxation of the pelvic muscles causes the pelvic floor to descend and the anorectal angle to straighten. Conscious inhibition of the external anal sphincter then allows passage of the feces. On completion, the pelvic floor returns to its resting position and the anal sphincter muscles return to their resting activity, closing the anal canal. Under normal circumstances, this process occurs once every 24 hours; however, the interval between bowel movements may vary between 8 and 12 hours and 2 to 3 days in normal subjects.

The frequency of defecation is influenced by multiple environmental and dietary factors. The gastrorectal reflex occurs as postprandial defecation. An increase in rectal tone results in increased pressure from the fecal mass on the rectal wall, providing heightened sensation.

Anal Continence

There are varying degrees of anal continence, with a spectrum from complete control to complete lack of control. Maintaining continence is complex, as both voluntary and involuntary mechanisms play a role in anal continence. The most important mechanisms involve the internal anal sphincter, which contributes 52% to 85% of the pressure generated to maintain continence.^{17,18} The rest of the contribution to the anal basal pressure includes the following: 30% from the external anal sphincter and

15% from the hemorrhoidal cushions. The internal sphincter is supplied by dual extrinsic innervation: sympathetic outflow (S5) via the hypogastric nerve provides motor supply and inhibition by parasympathetic outflow (S1–S3). The external sphincter nerve supply is dependent on the pudendal nerve (S2–S4) and maintains tonic activity at rest. When stool enters the rectum, the contents of the rectum are sampled by sensors in the anal canal to determine whether the contents are solid, liquid, or gas. By discriminating between the consistency of the stool, the pelvic floor and sphincter muscles are able to coordinate a complex mechanism through angulation of the pelvic floor and contraction of the anal sphincter muscles. Other mechanisms contributing to continence include stool consistency and volume. Modification of the stool consistency to more solid and less voluminous stool may allow a patient to recapture fecal control. Reservoir function of the rectum consists of lateral angulations of the sigmoid colon and the valves of Houston as a mechanical barrier to slow the progression of stool.

DISORDERS OF COLONIC MOTILITY AND ANAL CONTINENCE

Constipation

7 Constipation is common and may affect up to 15% of people, but only a portion of affected individuals seek medical help.¹⁹ Colorectal surgeons, gastroenterologists, gynecologists, and family medicine physicians are frequently called upon to treat constipation.²⁰ To evaluate constipation, the clinician must ask focused questions about bowel function. Constipation can mean infrequent bowel movements, straining, or hard stools. The Rome criteria were developed to help standardize the diagnosis (Table 64-1). Constipation can be caused by lifestyle choices, side effects of medications taken for other reasons, medical conditions (such as hypothyroidism), structural abnormalities of the colon, pelvic floor dysfunction, and colonic inertia (Table 64-2). Evaluation of the constipated patients includes a thorough history, a physical examination including a rectal examination, and evaluation for sources of pelvic floor dysfunction such as rectocele. Colonoscopy may be necessary to eliminate a structural bowel obstruction as the cause of constipation.

DIAGNOSIS

Table 64-1 Rome III Criteria for the Diagnosis of Constipation

Two or more of the following:
Straining in >25% of bowel movements
Incomplete evacuation of the rectum in >25% of bowel movements
Hard stool consistency in >25% of bowel movements
Three or fewer bowel movements weekly
Manual maneuvers in >25% of bowel movements
Sensation of anorectal obstruction in >25% of bowel movements
Do not meet the criteria for irritable bowel syndrome
Loose stools rarely present without the use of laxatives

From Longstreth GF, Thompson WG, Chey WD, et al. Functional bowel disorders. *Gastroenterology* 2006;130(5):1480–1491.

ETIOLOGY

Table 64-2 Causes of Constipation

Lifestyle
Inadequate fluid intake
Inadequate fiber intake
Inactivity
Laxative abuse
Medications
Anticholinergics
Antidepressants
Antihypertensive medications
Iron
Narcotics
Medical Conditions
Spinal cord dysfunction
Multiple sclerosis
Diabetes mellitus
Hypothyroidism
Uremia
Hypercalcemia
Electrolyte abnormality
Depression
Anorexia
Sexual abuse
Colon Abnormality
Cancer
Crohn disease
Chagas disease
Irradiation
Pelvic Floor Dysfunction
Nonrelaxing puborectalis
Anal stenosis
Rectocele

From Longstreth GF, Thompson WG, Chey WD, et al. Functional bowel disorders. *Gastroenterology* 2006;130(5):1480–1491.

After eliminating medication-related or metabolic causes of constipation and in the absence of systemic symptoms, it may be practical to initiate medical therapy before proceeding with radiologic testing for rare conditions such as colonic dysmotility or pelvic floor dysfunction. The goal of first-line medical therapy is to increase stool bulk and physical activity. Fiber intake should be increased to 20 to 30 g/d. To achieve this recommended daily amount, fiber supplementation with either psyllium or methylcellulose is frequently required. At least eight glasses of water should be ingested daily. Fiber and water intake increases stool bulk, and bulky bowel movements stimulate colonic motility. If fiber, water, and exercise do not relieve constipation, then laxatives should be added to the regimen. Laxatives can be divided into different categories by mechanism of action ([Table 64-3](#)). Osmotic laxatives are usually the first-line treatment for severe constipation. Long-term use of laxatives, which irritate the colon, should be avoided, however, because they can actually impair colon function. Melanosis coli, a dark discoloration of the colonic mucosa seen on colonoscopy, is a sign of frequent laxative use.

TREATMENT

Table 64-3 Laxatives

Bulking Agents (Soluble Fiber)
Psyllium (Konsyl, Metamucil)
Methylcellulose (Citrucel)
Calcium polycarbophil (FiberCon)
Colonic Stimulants/Irritants
Senna (Senokot and Peri-Colace)
Cascara
Bisacodyl (Dulcolax)
Stool Softeners
Mineral oil
Docusate sodium (Colace)
Osmotic Laxatives
Lactulose
Polyethylene glycol (MiraLAX)
Sodium phosphate (Fleets Phosphosoda)
Magnesium hydroxide (milk of magnesia)

Some patients whose constipation does not respond to standard medical therapy will be found to have slow-transit constipation or pelvic floor dysfunction, both of which require radiologic studies for diagnosis. The most common technique for evaluating colonic transit is a Sitz marker study (Fig. 64-6). To complete this test, all laxatives must be stopped 48 hours before the study. On day 0, a set number of radiopaque markers are ingested; an abdominal radiograph is obtained on day 1 to document that the markers were ingested and have passed through the small bowel into the colon, and again on day 5 to determine if the markers have been expelled. Normally, on day 5, more than 80% of the markers should be evacuated. If more than 20% of the markers remain and they are either clustered in the right colon or evenly distributed throughout the colon, the patient has slow-transit constipation. Outlet obstruction is suggested by clustering of the markers in the sigmoid or rectum. Outlet dysfunction can be further evaluated with defecography, a fluoroscopic study of defecation. Slow-transit constipation is best treated with surgery, and obstructed defecation with biofeedback therapy.

Figure 64-6. Sitz marker study demonstrating colonic inertia.

Postoperative Ileus

8 9 Postoperative ileus is transient impairment of bowel function after an operation. It is most common in patients after intra-abdominal surgical procedures, particularly colonic operations. Clinically, postoperative ileus is manifested by abdominal distention and delayed passage of flatus and, less

frequently, by nausea and vomiting. After an abdominal operation, the colon usually takes 3 to 5 days to recover, whereas the stomach and small bowel resume normal motor function more rapidly (1 to 2 days and 1 day, respectively).²¹ In a recent multicenter study, the average length of hospital stay after bowel resection was 6.6 days, with 11.5% of patients requiring a nasogastric tube for ileus.²² Postoperative ileus is multifactorial. Surgical and anesthetic technique, narcotic use, inactivity, and postoperative infectious complications all have been implicated in prolonged ileus. Bowel manipulation has also been suggested to contribute to the development of ileus.²² The observation that postoperative ileus is shorter after minimally invasive surgery adds credence to this theory.²³ Use of the anesthetic agent halothane, as well as opioid analgesics, can prolong postoperative ileus.²¹ After surgery, systemically administered morphine, in addition to binding to μ -opioid receptors in the central nervous system and promoting analgesia, binds to peripheral μ -opioid receptors in the colon and causes nonpropulsive electrical activity that can prolong ileus.²⁴ Given this, recent research has focused on strategies to minimize the use of perioperative narcotics with the goal of preventing or minimizing postoperative ileus. One of the most promising strategies is the use of a thoracic epidural for postoperative analgesia. In addition to delivering analgesia with minimal narcotics, thoracic epidural blocks promote parasympathetic activity by blunting sympathetic inhibition of the gut, thereby promoting gut motility. The greatest benefit is seen with epidural infusions of local anesthetic (lidocaine or bupivacaine), as compared to narcotics.²¹ Other benefits of using thoracic epidurals in the postoperative period are improved mental acuity and overall better pain control as compared to traditional narcotic-based regimens, both of which promote early mobility, particularly in elderly patients.²⁵ Alvimopan, an oral medication that blocks the μ -opioid receptors in the gastrointestinal tract, is the most studied medication to prevent postoperative ileus. A phase III multicenter study of patients who had a bowel resection or hysterectomy found that alvimopan (12 mg before surgery, then twice a day until discharge) decreased hospital stay by 18 hours as compared to placebo, in narcotic naïve patients.²⁶ As understanding of gut neurophysiology continues to improve, it is anticipated that more narcotic sparing pain regimens will be available for the management of postoperative pain.

Enhanced recovery protocols are increasingly gaining traction in the United States. Initially called Fast Track Surgery by Wilmore and Kehlet,²⁷ and later Enhanced Recovery After Surgery (ERAS), they focus on incorporating evidence-based treatments into clinical pathways with a particular emphasis on multimodal pain management and avoidance of narcotics.²⁸ General principles of enhanced recovery protocols include preoperative education, avoidance of preoperative fasting and postoperative nasogastric tubes, early introduction of enteral feeding, avoidance of parenteral narcotic analgesia.²⁹ The enhanced recovery protocols accelerate surgical recovery and are associated with reductions in length of hospital stay and decreased 30 postoperative morbidity including infectious complications and postoperative ileus.^{30–33} In order to implement protocols and maintain high levels of compliance, enhanced recovery requires a multidisciplinary team approach with surgeons, anesthesia providers, nurses and care coordinators collaborating for both the implementation and sustaining of the protocol. Patient engagement and preoperative expectation setting is essential. Most successful programs have developed enhanced recovery focused educational materials and report marked increase in patient satisfaction postprotocol implementation.

Irritable Bowel Syndrome

Irritable bowel syndrome is defined as abdominal pain that is not associated with an anatomic abnormality and may or may not be associated with alterations in bowel habits. The causes of this disorder are uncertain. Emotional stress and psychiatric illness have been implicated in the pathogenesis of the disorder and may exacerbate symptoms.³⁴ Physiologic abnormalities have also been demonstrated, as has abnormal colonic motility in response to an ingested meal.³⁵ Altered myoelectric activity and abnormal gut hormone secretion have also been cited as potential causes.

Because no one, clear cause of irritable bowel syndrome has been demonstrated, no specific treatment regimen has been defined for this disorder. Most patients have asymptomatic periods interrupted by intervals of symptoms. The approach to treatment begins with an evaluation of the factors associated with irritable bowel syndrome. Diagnosis and treatment of an underlying psychiatric problem may resolve the patient's symptoms. A detailed dietary history should also be taken, and factors that contribute to constipation or diarrhea should be adjusted appropriately. If these management strategies are not successful, gradually introducing anticholinergic medications may be helpful. Anticholinergic agents can reduce the rate of myoelectric activity and decrease tonic contractions in the colon, thereby relieving the cramping and bloating that many patients experience. Low doses of tricyclic

antidepressants, including imipramine, amitriptyline, and nortriptyline, often decrease or eliminate abdominal symptoms. Constipation is known to be one major side effect of these agents, which may be helpful in patients with irritable bowel syndrome and underlying diarrhea, but a problem in patients with pre-existing constipation. The myriad treatment options described for irritable bowel syndrome underscores the poor understanding of this clinical entity.

Colonic Pseudo-obstruction

Colonic pseudo-obstruction, also known as *Ogilvie syndrome*, is massive dilation of the colon without an actual mechanical obstruction. In 1948, Ogilvie described two patients with colonic pseudo-obstruction from malignant infiltration of the celiac plexus that he postulated led to sympathetic inhibition.³⁶ In the intestine, stimulation of the sympathetic nervous system decreases intestinal motility, whereas activation of the parasympathetic nervous system promotes contractility. Colonic pseudo-obstruction results from an imbalance in the autonomic nervous system of the gastrointestinal tract. Various metabolic conditions, pharmacologic agents, and traumatic factors can alter the balance of the intestinal autonomic nervous system and have been associated with colonic pseudo-obstruction.³⁷ The most frequent presenting symptoms are abdominal pain and nausea and vomiting. On physical examination, the abdomen is distended and tympanic and may be mildly tender when palpated. Marked colonic distention present on an abdominal radiograph is the hallmark of the condition ([Fig. 64-7](#)). Fever and leukocytosis are rare and should raise the concern for perforation.³⁸ First-line management of colonic pseudo-obstruction is conservative and consists of nasogastric decompression, cessation of oral feedings, correction of fluid and electrolyte imbalances, and avoidance of narcotics and anticholinergics. If abdominal radiographs do not show gas throughout the colon, an abdominal computed tomography scan or a Gastrografin enema should be considered to rule out a mechanical obstruction. With conservative measures, colonic pseudo-obstruction resolves in more than 75% of cases. When the pseudo-obstruction persists for more than 6 days and/or the diameter of the cecum on abdominal radiograph is greater than 12 cm, the risk for cecal perforation increases.^{38,39}

Figure 64-7. Pseudo-obstruction of the colon (Ogilvie syndrome).

Colonic pseudo-obstruction is most commonly seen in elderly patients who may have other significant medical conditions, so when free perforation occurs, it can be associated with significant morbidity and mortality (up to 40% in one study).⁴⁰ In patients whose pseudo-obstruction is not responding to conservative therapy but who have no signs of peritonitis, 2.5 mg of neostigmine given intravenously over 2 to 3 minutes has been found to decompress the colon promptly in nearly all patients.^{41,42} Neostigmine is a reversible acetylcholinesterase inhibitor that stimulates the intestinal parasympathetic receptors, promoting colonic motility.⁴³ In a randomized controlled study, the pseudo-obstruction resolved promptly in 10 of 11 patients.⁴¹ If neostigmine fails to decompress the colon, another

alternative is decompressive colonoscopy. In one series, 69% of patients had resolution of their pseudo-obstruction after colonoscopy to remove air.⁴³ Surgery is reserved for patients with obvious peritoneal signs or whose pseudo-obstruction has not improved after all forms of nonsurgical therapy. In such patients, when the possibility of cecal perforation is high, a cecostomy can be considered.

Anal Incontinence

Anal incontinence is defined as the inability to control the passage of gas, liquid, or solid stool. Obstetric trauma from vaginal deliveries is the most common cause of fecal incontinence in adult women.¹ Occult sphincter injury is reported in 25% to 35% of women on endoanal ultrasound after delivery. Vaginal deliveries that require forceps/vacuum-assistance and/or episiotomies are associated with increased risk of subsequent fecal incontinence. Others include aging, anorectal surgery, inflammatory bowel disease, infectious proctitis, anal or rectal neoplasm, congenital malformations (e.g., spina bifida, imperforate anus, myelomeningocele), traumatic injury, sequelae of radiation, underlying neurologic disorders (diabetes, multiple sclerosis, pudendal neuropathy and fecal impaction).

Workup consists of obtaining a history focusing on the above etiologic factors, evaluation and optimization of underlying medical conditions, documentation of bowel habits, and further characterization of the incontinence. It is important to establish if other pelvic floor disorders are present as well by eliciting symptoms of rectal and pelvic organ prolapse, as well as urinary incontinence. The most common scoring system to quantitate fecal incontinence is the Cleveland Clinic Florida Fecal Incontinence Score (CCF-FIS) (Table 64-4).^{44,45} Physical examination should note anal sphincter tone, as well as associated scars from prior anorectal surgery or vaginal delivery. Physiologic studies to assess incontinence complement the history and physical examination and include anorectal manometry for evaluation of anal sphincter function, and endoscopic ultrasound for detection of occult sphincter defects. Other diagnostic studies to consider, based on symptoms include defecography (to evaluate for pelvic organ prolapse), and colonoscopy (to diagnose occult malignancy or inflammatory bowel disease).

Table 64-4 Cleveland Clinic Incontinence Score

	Never	Rarely	Sometimes	Usually	Always
Incontinence for solid stool	0	1	2	3	4
Incontinence for liquid stool	0	1	2	3	4
Incontinence for gas	0	1	2	3	4
Alteration in lifestyle	0	1	2	3	4
Need to wear a pad or plug	0	1	2	3	4

Never = 0
Rarely ≤1/month
Sometimes <1/week, >1/month
Usually ≤1/day, >1/week
Always ≥1/day
0 = perfect
20 = complete incontinence

Initial management is conservative and consists of medication to optimize bowel and biofeedback to ensure that the anal muscles are squeezing appropriately. A trial with bulking agents, such as fiber and constipating agents is effective for many patients with loose stools and incontinence; bulky, soft stools are easiest for the anal sphincter muscles to retain. For patients with incontinence related to fecal impaction, a laxative regimen including enemas and scheduled disimpactions can improve control. Biofeedback is a form of physical therapy that retrains muscle (external sphincter and pelvic floor muscles) and facilitates anal-neuro feedback for discrimination of rectal sensations. Biofeedback has been shown to improve fecal incontinence in 50% to 86% of patients.^{46–49} Because it is safe, inexpensive, and effective, biofeedback should be offered to all patients who do not respond to medical therapy.

10 The most common surgical interventions are overlapping sphincteroplasty, injectable agents, sacral nerve stimulation (SNS), and colostomy. Traditionally, overlapping sphincteroplasty has been the standard of care for patients with fecal incontinence and a sphincter defect on imaging studies. Short-term success rates have been as high as 70%; however, long-term functional outcomes are poor.^{50–55} A newer option, injectable agents augment the anal cushions and are used for mild to moderate degrees of passive fecal incontinence. Different biomaterials have been used but the most common is SOLESTA (hyaluronic acid/dextranomer) (Salix Pharmaceuticals, Inc). Complications are minor and self-limiting

and include proctalgia and/or pain at the injection site, local bruising and inflammatory reaction. Efficacy data are sparse but one large randomized controlled trial demonstrated improvement in continence for half the patients treated with SOLESTA.⁵⁶ The FDA-approved SNS for treatment of fecal incontinence in 2011. It is a two-stage procedure, in which there is a trial period, involving percutaneous implantation of an electrode into S3. If there is a >50% improvement in symptoms, the patient proceeds to the second stage which involves placement of a permanent stimulator. Between 50% and 92% success rates have been reported with an improvement of $\geq 50\%$ reduction in the number of incontinent episodes per week compared to baseline. Perfect continence has been achieved in 40% of subjects.^{57–68} Since SNS was approved, it has largely replaced overlapping sphincteroplasty as the first line treatment. Finally, colostomy is a last resort in patients in whom all other treatment modalities have failed.

SUMMARY

The colon, rectum, anus all help coordinate very complicated functions. Understanding their physiology is important in the management of their associated pathology.

Chapter 65

Acute Gastrointestinal Hemorrhage

Jason S. Mizell and Richard H. Turnage

Key Points

- 1 Upper gastrointestinal (UGI) hemorrhage accounts for about 80% of cases of acute GI blood loss.
 - 2 The most common cause of acute UGI hemorrhage is peptic ulcer disease and the most common cause of acute lower gastrointestinal (LGI) hemorrhage is diverticulosis.
 - 3 Upper GI bleeding typically presents with hematemesis (the vomiting of blood) or melena (the passage of black, tarry stool), whereas lower GI bleeding typically causes hematochezia (the passage of fresh blood from the rectum).
 - 4 Most patients (about 80%) suffering from GI hemorrhage will stop bleeding spontaneously. Those who do not stop or those who rebleed are at particularly high risk to suffer an in-hospital complication, require operative control of their hemorrhage, or die.
 - 5 Esophagogastroduodenoscopy (EDG) is the initial diagnostic study of choice for patients suspected of bleeding from the esophagus, stomach or duodenum and colonoscopy is the procedure of choice for evaluating patients with a suspected lower GI hemorrhage.
 - 6 Nonsteroidal anti-inflammatory drugs are an important risk factor for the development of GI hemorrhage in general and gastroduodenal ulcer formation in particular.
 - 7 Treatment of patients bleeding from gastroduodenal ulcer is intravenous proton pump inhibitor and endoscopic thermocoagulation or mechanical ligation or clipping of the bleeding vessel.
 - 8 In general, a patient bleeding from esophageal varices should undergo urgent pharmacologic therapy with intravenous octreotide and endoscopic banding of the bleeding varices.
 - 9 Lower GI hemorrhage due to diverticulosis is generally managed nonoperatively due to a low risk of persistent or recurrent bleeding.
-

1 Acute gastrointestinal (GI) hemorrhage is categorized as upper or lower depending upon the location of the bleeding relative to the ligament of Treitz. Upper GI (UGI) hemorrhage (i.e., bleeding from the esophagus, stomach, or duodenum) accounts for about 80% of cases of acute GI blood loss, with most of the remainder coming from the colon. The small intestine is the site of hemorrhage in about 1% to 5% of cases.^{1,2} Although it may be decreasing,³ the incidence of UGI bleeding is estimated to be about 37 to 150 episodes per 100,000 individuals depending upon the population sampled,⁴ whereas the incidence of lower GI (LGI) bleeding is about 20 cases per 100,000 individuals.⁵ Overall, GI hemorrhage accounts for roughly 300,000 hospitalizations and 30,000 deaths annually in the United States.⁶

2 The differential diagnosis of overt UGI and LGI hemorrhage and the relative frequency of the most common causes of GI bleeding are shown in [Tables 65-1](#) and [65-2](#) and [Figure 65-1A,B](#), respectively. Although the incidence varies by age, overall the most common causes of acute UGI hemorrhage are peptic ulcer disease (31% to 58%), gastritis and mucosal erosions (9% to 30%), and gastroesophageal varices (3% to 23%)^{1,4} whereas diverticulosis (24% to 47%), all forms of colitis (6% to 26%), neoplasms (9% to 17%), and angiodysplasia (2% to 12%) account for most instances of lower GI hemorrhage.^{1,5,7-10}

PATIENT CHARACTERISTICS

Patients who suffer significant GI hemorrhage are more commonly older (average age approximately 60 to 70 years)^{1,4} and male compared with individuals without GI bleeding. Furthermore, these individuals are more likely to use alcohol, tobacco, aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and anticoagulants.^{1,11} Predictors of risk for acute GI bleeding are shown in [Table 65-3](#).

Coexisting chronic illnesses are common in patients suffering either a UGI or LGI hemorrhage.

Various studies have suggested a correlation between GI bleeding and correlates of poor health such as the use of multiple medications, reduced levels of physical activity, and inability to complete basic self-care tasks.¹¹ Cardiovascular,¹¹ hepatic, and renal disease¹² are particular risk factors for acute GI bleeding. The presence of these chronic illnesses, as well as chronic obstructive pulmonary disease and cirrhosis, also greatly increase the risk of rebleeding after endoscopic control.¹³ Tobacco is also associated with higher rates of significant GI hemorrhage. A prospective cohort study of 5,888 men and women found that the multivariate-adjusted hazard ratio for subjects who smoked more than half a pack per day was 2.14 (95% CI = 1.22, 3.75) for UGI bleeding.¹¹

Certain medications increase the risk of GI hemorrhage. Many studies have related the use of NSAIDs and aspirin to significant GI bleeding. The risk is particularly elevated for UGI bleeding but NSAIDs increase the risk of LGI hemorrhage as well. In Vreeburg’s review of 951 patients with UGI hemorrhage, 41% used NSAIDs or aspirin. Van Leerdam reported that more than half of the patients bleeding from ulcers were actively taking NSAIDs or ASA.¹⁴ Mellemkjaer et al.¹⁵ found that the observed to expected ratio of UGI hemorrhage in a cohort of 156,138 users of NSAIDs was 4.1 (95% CI = 3.8, 4.5). Other medications known to increase the risk of GI hemorrhage include corticosteroids, spironolactone,¹⁶ and the selective serotonin reuptake inhibitors (SSRIs).^{17,18}

The use of anticoagulants is also an important risk factor for acute GI bleeding. Coumadin is a particularly common cause. Kaplan found the age- and sex-adjusted hazard ratio for GI bleeding in patients taking oral anticoagulants was 2.59 (95% CI = 1.71, 3.93).¹¹ Vreeburg et al.⁴ reported that 17% of their patients with UGI hemorrhage were taking coumadin and the international normal ratio (INR) was greater than 4 in more than half of these patients. Because coumadin metabolism can be affected by so many interfering substances, inadvertent coumadin toxicity is a common problem, often presenting with GI hemorrhage. Antiplatelet agents such as clopidogrel and ticlopidine are also associated with an increased risk of GI hemorrhage.¹⁹

Table 65-1 Differential Diagnosis of Acute Upper Gastrointestinal Hemorrhage by Anatomic Site

Esophagus	Duodenum
Esophagitis	Peptic ulcer disease
Reflux	Duodenal ulcer
Infectious (fungal, viral)	Arteriovenous malformation
Esophageal varices	Neoplasms
Neoplasms	Lymphoma
	GI stromal tumors
Stomach	Duodenal adenocarcinoma
Peptic ulcer disease	Pancreatic adenocarcinoma
Gastric ulcer	Carcinoid tumors
Gastroesophageal varices	Dieulafoy ulcers
Portal gastropathy	Aortoduodenal fistula
Gastric antral vascular ectasia (watermelon stomach)	Diverticula
Dieulafoy ulcer	
Arteriovenous malformation	Hepatopancreatic-biliary
Neoplasms	Hemobilia
GI stromal tumors (leiomyoma, leiomyosarcoma)	Pancreatitis-induced pseudoaneurysm
Lymphoma	
Adenocarcinoma	
Carcinoid tumors	
Mallory–Weiss Tear	
Stress gastritis	

CLINICAL PRESENTATION

3 The presentation of GI bleeding can range from mild asymptomatic bleeding to overt GI bleeding. UGI bleeding typically presents with hematemesis (the vomiting of blood) or melena, whereas LGI bleeding typically presents with hematochezia. Melena is a black, tarry stool resulting from the degradation of blood by enteric bacteria. It may occur with the loss of as little as 50 to 200 mL of blood.^{20,21} Bleeding from the small intestine or right colon may also appear black if it has remained in the GI tract for more than 12 to 14 hours.²² Hematochezia is the passage of bright red blood, maroon-colored blood, or blood clots from the rectum. However, massive UGI hemorrhage can cause

hematochezia in as many as 11% of patients, but this is typically associated with hemodynamic instability.²³ Patients with acute GI bleeding may present with the hemodynamic consequences of hemorrhage including light-headedness, dizziness, orthostatic syncope or near syncope, shortness of breath, or palpitations from tachycardia.

Table 65-2 Differential Diagnosis of Acute Lower Gastrointestinal Hemorrhage by Anatomic Site

Small Intestine	Colon and Rectum
NSAID-induced ulcers	Diverticulosis
Diverticula	Colitis
Meckel diverticula	Crohns disease
Pseudodiverticula	Ulcerative colitis
Neoplasms	Radiation colitis
Lymphoma	Infectious colitis
GI stromal tumors	Ischemic colitis
Adenocarcinoma	Neoplasms
Carcinoid tumor	Adenocarcinoma
Inflammation	GI stromal tumors
Crohn disease	Lymphoma
Radiation enteritis	Carcinoid tumors
Ischemic enteritis	Arteriovenous malformation
Infectious enteritis	Iatrogenic
Arteriovenous malformations	Polypectomy sites
Aortoenteric fistula	Benign rectal diseases
	Hemorrhoids
	Rectal ulcers

Figure 65-1. A: The relative frequency of the most common causes of upper gastrointestinal hemorrhage in the United States. These data represent the percentage of patients with each of these causes of UGI hemorrhage for 482 patients in a survey of the members of the American College of Gastroenterology published by Peura et al.¹ in 1997. These data are very similar to that reported by Vreeburg in a multi-institutional study of 951 patients sustaining a UGI hemorrhage in the hospitals in and surrounding Amsterdam.⁴ **B:** The relative frequency of the most common causes of lower gastrointestinal hemorrhage. These data, reported by Lingenfelser and Ell⁵ are the percentage of patients with each of these causes of lower GI hemorrhage in 912 patients collected in five studies from Europe, the Orient, and the United States^{1,7-10}

The medical history and physical examination provide important clues of the etiology of the patient’s hemorrhage and the potential risk to the patient’s life. The occurrence of melena after several days of worsening epigastric or upper abdominal pain suggests peptic ulcer disease; whereas hematemesis or melena following vomiting or retching strongly suggests a Mallory–Weiss tear. Massive, painless UGI hemorrhage in a patient with cirrhosis suggests bleeding from gastroesophageal varices, although other etiologies including peptic ulcer disease or a Mallory–Weiss tear must also be considered. The medical history should elicit the presence of risk factors for GI hemorrhage alluded to in the previous paragraphs and in [Table 65-3](#) .

A systematic physical examination will document the magnitude of bleeding and the patient’s ability to compensate. Massive hemorrhage is associated with signs and symptoms of hypovolemic shock, including cool, clammy, mottled skin, tachycardia, tachypnea, flat jugular veins, oliguria, and perhaps hypotension. These responses may be altered by advanced age, concomitant medical problems, and particular medications. Physical examination should also document evidence of cirrhosis and portal hypertension (i.e., ascites, spider angiomas, hepatosplenomegaly, palmar erythema, and large hemorrhoidal veins). A rectal examination may demonstrate bright red blood or melena. The clinical scenario alone will usually not localize the location of the bleeding, so other diagnostic studies are often required to identify the cause and site of bleeding.

PROGNOSTIC FACTORS

4 Most patients (approximately 80%) suffering from GI hemorrhage will stop bleeding spontaneously. Those who do not stop or those who rebleed are at particularly high risk to suffer an in-hospital complication, require operative control of their hemorrhage, or die. Several classification systems have been developed to separate patients with low risk of complications from those with a high risk of complications due to acute UGI and LGI hemorrhage. These systems have also been used to stratify those patients who may be safely managed as an outpatient from those requiring in-hospital care.²⁴ The BLEED classification system addresses both UGI and LGI hemorrhage and consists of the following parameters: ongoing bleeding, low systolic blood pressure, elevated prothrombin time, erratic mental status, and unstable comorbid disease. Patients with at least one BLEED criterion are more likely to suffer in-hospital complications from UGI bleeding (31% vs. 4%) or LGI bleeding (38% vs. 12%) than are patients with no criteria.²⁵

Table 65-3 Characteristics of Individuals at an Increased Risk of Developing Acute Gastrointestinal Bleeding

Increased Age
Male sex
Unmarried (vs. married)
Perceived fair or poor health status
Cardiovascular disease
Diabetes mellitus
Renal disease
Difficulty with activities of daily living
Low level of physical activity
Increased numbers of medications
Oral anticoagulant use

Table 65-4 Rockall Risk Scoring System and Rates of Rebleeding and Mortality

Variable	Score								
	0			1		2		3	
Age	<60 yrs			60–79 yrs		≥80 yrs			
Shock	“No shock” Systolic blood pressure ≥100 Heart rate <100			“Tachycardia” Systolic blood pressure ≥100 Heart rate ≥100		“Hypotension” Systolic blood pressure <100			
Comorbidity	None			None		Cardiac failure Ischemic heart disease Any major comorbidity		Renal failure Liver failure Disseminated malignancy	
Diagnosis	Mallory–Weiss tear No lesion identified No stigmata of recent hemorrhage			All other diagnosis		Malignancy of the upper GI tract			
Major stigmata of recent hemorrhage	None or dark spot only					Blood in upper GI tract Adherent clot Visible or spurting vessel			
Score	0	1	2	3	4	5	6	7	8+
Percent mortality	0	0	0.2	2.9	5.3	10.8	17.3	27	41

From Rockall TA, Logan RF, Devlin HB, et al. Risk assessment after acute upper gastrointestinal haemorrhage. *Gut* 1996;38:316–321.

Prognostic systems for UGI hemorrhage have been more widely adopted than those for LGI hemorrhage. One widely used system is the Rockall score for assessing the risk of death and rebleeding in patients with UGI hemorrhage (Table 65-4). Using this model, Rockall et al. found that rebleeding occurred in less than 5% of patients and mortality was virtually zero (0% to 0.2%) in patients with scores of 0 to 2. In contrast, a fourth to nearly one-half of patients with a Rockall score of 5 to 8+ rebled; the mortality rate for these patients was 11% to 41%. In this study, rebleeding significantly affected the likelihood of death, particularly for patients with intermediate scores of 3 or 4 and 5 to 7 in which there was a three- to fivefold increase in mortality rates.²⁶

The Rockall classification has been widely accepted as accurate and importantly has been externally validated.^{27–30} However, the full classification scheme requires endoscopic assessment. An alternative scoring system – the Glasgow–Blatchford bleeding score (GBS) – is based on clear and readily available clinical and laboratory indices without the need for endoscopy Table 65-5. It was designed to predict need for clinical intervention due to UGI hemorrhage. This scoring system has been subjected to multi-institutional trials and found to be at least as effective as and possibly more accurate than the Rockall system.^{31,32} These authors suggested that patients with a score of 0 can be safely managed as outpatients.

Conversely, patients with LGI bleeding typically present with less hemodynamic instability. Factors that is indicative of a severe lower GIB thus necessitating more urgent intervention include:

- Heart rate > 100/min
- Initial systolic blood pressure 115 mm Hg or less
- History of syncope
- Nontender abdominal examination
- Bleeding per rectum during the first 4 hours of evaluation
- History of aspirin use
- Charlson Comorbidity Index score of more than 2.³³

INITIAL EVALUATION AND RESUSCITATION

Upon presentation, two large-bore intravenous lines should be placed in peripheral veins and intravascular volume resuscitation begun with an isotonic saline solution. Most patients stop bleeding spontaneously, and crystalloid volume resuscitation is all that is required. Blood is drawn for type and crossmatch, complete blood count with platelet count, electrolyte measurement, liver function tests, and coagulation profiles. It is important to emphasize that on presentation, the hematocrit or hemoglobin level may not accurately reflect the magnitude of acute blood loss. Estimates of the severity of hemorrhage must be based on clinical parameters.

The massively bleeding patient should receive packed red blood cells (RBCs) to restore intravascular volume and oxygen-carrying capacity. The decision to transfuse blood or blood products depends on the

individual needs of the patient and the cause of the bleeding. The risks of the blood products (i.e., infection and allergic reactions) must be weighed against the risks of withholding transfusion (i.e., anemia, decreased oxygen-carrying capacity, coagulopathy). In general, blood products are used early in the management of patients with limited cardiac and pulmonary reserve (who are unable to withstand or compensate for an acute reduction in their systemic oxygen delivery) and those with lesions that are at particular high risk for continued or recurrent hemorrhage (e.g., gastroesophageal varices).

Careful hemodynamic monitoring of these potentially critically ill patients is vital to successful management. There are no clear recommendations, but it seems reasonable for those patients who are actively bleeding and those who have recently sustained significant hemorrhage to be admitted to an intensive care unit for close monitoring of hemodynamic parameters and evidence of continued or recurring hemorrhage. The presence of significant underlying illnesses, such as cardiac, renal, hepatic, or pulmonary insufficiency, may necessitate noninvasive monitoring or invasive cardiac monitoring with central venous and arterial catheters. The information gained from these devices allows cardiac performance to be optimized during intravascular volume replacement. The placement of a urinary catheter and frequent monitoring of heart rate, blood pressure, urine output, and mental status are the minimum necessary to monitor patients who have suffered GI hemorrhage. The importance of prompt, adequate resuscitation and diligent observation cannot be overemphasized as the cornerstone for managing these potentially mortally ill patients.

Table 65-5 Glasgow–Blatchford Bleeding Score (GBS)

	Score Value		Score Value
Blood Urea (mmol/L)		Systolic Blood Pressure (mm Hg)	
<6.5	0	100–109	1
6.5–7.9	2	90–99	2
8.0–9.9	3	<90	3
10.0–25.0	4		
>25.0	6	Other Markers	
Hemoglobin for Men (g/L)		Pulse <100	0
≥130	0	Pulse ≥100/min	1
120–129	1	Presentation with melena	1
100–119	3	Presentation with syncope	2
<100	6	Hepatic disease ^a	2
Hemoglobin for Women (g/L)		Cardiac failure ^b	2
≥120	0	Absence of melena, syncope, hepatic disease or cardiac disease	0
100–119	1		
<100	6		

^aKnown history, or clinical and laboratory evidence, of chronic or acute liver disease.

DIAGNOSTIC APPROACH

5 After the restoration of circulating blood volume, the next step is to identify the source of bleeding so that definitive therapy may be instituted. If the patient presents with hematemesis, localization of the bleeding to the esophagus, stomach, or duodenum is relatively straightforward and esophagogastroduodenoscopy (EGD) should be performed promptly to identify the source of bleeding. When blood or coffee-ground guaiac-positive material is present in the gastric aspirate, EGD will likely define the site of bleeding. Bright red blood per rectum strongly suggests a lower GI source of bleeding unless the patient is hemodynamically unstable in which case the hemorrhage may originate from a source proximal to the ligament of Treitz. A general algorithm for evaluating patients with acute UGI and LGI hemorrhage is presented in [Algorithm 65-1](#).

Algorithm 65-1

Algorithm 65-1. Diagnostic steps in the evaluation of gastrointestinal hemorrhage.

Table 65-6 Predictors of Persistent or Recurrent Bleeding in Patients with Nonvariceal UGI Hemorrhage

	Range of Odds Ratios for Increased Risk
Clinical Factors	
Age >65 yrs	1.3
>70 yrs	2.30
Shock (systolic blood pressure <100 mm Hg)	1.2–3.65
Health status (ASA Class 1 vs. 2–5)	1.94–7.63
Comorbid illness	1.6–7.63
Erratic mental status	3.21 (95% CI: 1.53, 6.74)
Ongoing bleeding	3.14 (95% CI: 2.40–4.12)
Laboratory Factors	
Initial hemoglobin <10 gm/dL or hematocrit <0.30	0.8–2.99
Coagulopathy (prolonged partial thromboplastin time)	1.96 (95% CI: 1.46, 2.64)
Presentation of Bleeding	
Melena	1.6 (95% CI: 1.1, 2.4)
Red blood on rectal examination	3.76 (95% CI: 2.26, 6.26)
Blood in gastric aspirate or stomach	1.1–11.5
Hematemesis	1.2–5.7
Endoscopic Factors	
Active bleeding on endoscopy	2.5–6.48
Endoscopic high-risk stigmata	1.91–4.81
Clot	1.72–1.9
Ulcer size ≥2 cm	2.29–3.54
Diagnosis of gastric or duodenal ulcer	2.7 (95% CI: 1.2, 4.9)
Ulcer location	
High on lesser curvature	2.79
Superior wall of duodenal bulb	13.9
Posterior wall of duodenal bulb	9.2

Gastric Aspiration

Recent studies have called into question the routine placement of nasogastric tubes (NGTs) in all

patients with suspected GI bleeding. In patients with hematemesis, gastric aspiration is not necessary to obtain a diagnosis of a UGI bleed. However, it can provide useful information regarding the rate of hemorrhage. Knowing the degree to which a patient is bleeding may help guide clinical decision making, such as the need to initiate octreotide, transfuse blood emergently, urgently perform an EGD, or determine whether or not ICU monitoring is necessary.³⁴

In the absence of hematemesis, aspiration of gastric fluid after the placement of a NGT may be used to distinguish between a UGI and LGI source of bleeding. Two studies with more than 700 patients found that the presence of blood in the gastric aspirate was a good indicator of a UGI source; however, its absence was unreliable in predicting the presence or absence of a UGI source.^{35,36} In one study of 220 patients with UGI sources of bleeding, the sensitivity, specificity, and accuracy of the nasogastric aspirate was 42% (95% confidence interval [CI] = 32, 51%), 91% (95% CI = 83, 95%), and 66% (95% CI = 59, 72%), respectively.³⁶ While a clear aspirate does not rule out a UGI source of bleeding, aspiration of blood confirms it. Additionally, placing an NGT may help remove blood from the gastric lumen to improve visualization once the EGD is performed. However, NGT placement can be associated with pain, aspiration, and pneumothorax.³⁷ Additionally, other less invasive methods may indicate a UGI source (black stool, BUN/creatinine ratio >30, and age younger than 50 years). Due to these factors, NGT placement prior to EGD should not be routine but instead individualized to each patient.

Endoscopy

Esophagogastroduodenoscopy

EGD will identify the site of bleeding in about 95% of cases of UGI bleeding and is the initial diagnostic study for patients suspected of bleeding from the esophagus, stomach, or duodenum.³⁸ The sensitivity of the procedure is significantly enhanced when performed within the first 24 hours of presentation.⁴ A systematic review of the literature found that early endoscopy (i.e., performed within 24 hours of admission) was associated with a decreased transfusion requirement and decreased length of stay.³⁹ A prospective, randomized trial found that early endoscopy allowed the triaging of 46% of patients to outpatient care without any adverse effects.⁴⁰ Previous consensus guidelines and several cohort studies have related various endoscopic stigmata of recent or active hemorrhage to a heightened risk of rebleeding or continued bleeding.^{41–44} Laine and Peterson⁴¹ analyzed data from 37 prospective trials in which patients with bleeding ulcers did not receive endoscopic therapy; they found that the rate of further bleeding was less than 5% for those patients with a clean ulcer base and increased to 10% for patients with a flat spot, 22% for those with an adherent clot, 43% for those with a nonbleeding visible vessel, and 55% for those with active bleeding. Endoscopic features predictive of persistent or recurrent bleeding and mortality are shown in [Tables 65-6, 65-7, and 65-8](#). In addition to these ulcer-specific factors, endoscopy allows identification of lesions with a high risk of continued hemorrhage and mortality (i.e., gastroesophageal varices), and those with a low risk (e.g., Mallory–Weiss tears). The efficacy of endoscopy-based modalities to control UGI hemorrhage is discussed in subsequent sections.

Colonoscopy

Although the efficacy of colonoscopy in determining the cause of occult GI bleeding is undisputed, historically its role in the evaluation of patients with acute LGI bleeding was less well agreed upon. Recently however, newer studies have established it as the procedure of choice for patients with suspected LGI bleeding despite its limitations.^{45–48} Colonic lavage with a polyethylene glycol solution can be used to clear the lumen of clot and stool providing adequate visualization of the mucosa,⁴⁹ but others have reported good visualization of the mucosa even in the absence of mechanical bowel preparation.⁵⁰

Studies have shown a diagnosis is made in 74% to 100% of patients with an LGI bleed undergoing colonoscopy, and a pool analysis of six recent studies found a composite yield of 91% for colonoscopy.^{47,48,51,52} A meta-analysis examined the role of colonoscopy as the primary diagnostic modality for patients with acute lower GI bleeding and found that 69% (range 48% to 90%) of urgent colonoscopies identified a source or a presumptive source of bleeding.⁵³ Even in the setting of unprepped bowel, urgent colonoscopy has been shown to identify bleeding colon and distal ileal lesions in 82 of 85 patients (97%).⁵⁰ Stigmata of recent hemorrhage for LGI bleeding are similar to those of UGI lesions and include an actively bleeding site, a nonbleeding visible vessel, and an adherent clot; these findings have been associated with continued hemorrhage and therefore the need for urgent colectomy.^{7,54} Jensen et al.⁴⁵ reported that 25% to 50% of patients with *any* of these three factors continued to bleed or rebled and ultimately required urgent colectomy. Others have found colonoscopy

to be less accurate in the diagnosis of LGI bleeding, for example, Al Qahtani et al.⁵⁵ reported a series of 136 patients in which colonoscopy identified only 45% of the sources of bleeding.

Enteroscopy

For those patients who present with hematochezia in whom the initial EGD and colonoscopy is nondiagnostic, repeating these studies before evaluating the small intestine is warranted given the very small frequency in which the bleeding originates from the small intestine (1%). Repeating the EGD and colonoscopy when the patient is better resuscitated will often detect lesions such as ulcers or vascular ectasias that were obscured by blood at the initial endoscopy or the vasoconstriction of the GI mucosa that accompanies hemorrhagic shock.

Endoscopy of the small bowel with an enteroscope or a pediatric colonoscope will allow inspection of the proximal 60 cm of the jejunum⁵⁶ and the use of a long videoenteroscope may allow visualization of 100 to 150 cm of intestine beyond the ligament of Treitz.⁵⁷ Jensen et al.⁵⁸ in an experience with more than 200 patients with obscure sources of GI bleeding reported success in identifying the etiology in 79% of instances using enteroscopy. In their experience, vascular ectasias and postbulbar ulcers were the most common causes of obscure GI bleeding.

Table 65-7 Predictors of Mortality in Patients with Nonvariceal UGI Hemorrhage

	Range of Odds Ratios for Increased Risk
Clinical Factors	
Age 60–69 yrs	3.5 (95% CI: 1.5, 4.7)
≥70 yrs	4.5–12.7
>80 yrs	5.7 (95% CI: 2.9, 10.2)
Shock (systolic blood pressure <100 mm Hg)	1.18–6.4
Health status (ASA class 1 vs. 2–5)	2.6–9.52
Comorbid illness	1.19–12.1
Continued or rebleeding	5.29–76.23
Sepsis	5.4 (95% CI: 1.5, 19.6)
Presentation of bleeding	
Red blood on rectal examination	2.95 (95% CI: 1.29, 6.76)
Blood in gastric aspirate or stomach	0.43–18.9
Hematemesis	2.0 (95% CI: 1.1, 3.5)
Onset of bleeding while hospitalized for other causes	2.77 (95% CI: 1.64, 4.66)
Laboratory Factors	
Elevated blood urea nitrogen level	5.5–18
Elevated serum creatinine level	14.8 (95% CI: 2.6, 83.5)
Elevated serum aminotransferase levels	4.2–20.2

ASA, American Society of Anesthesiologists.
From Barkun A, Bardou M, Marshall JK, et al.. Consensus recommendations for managing patients with nonvariceal upper gastrointestinal bleeding. *Ann Intern Med* 2003;139:843–857.

Intraoperative enteroscopy using a combination of push enteroscopes *per os* and *per rectum* or via enterotomy can allow examination of the entire small bowel. While the endoscopist manipulates the scope, the surgeon manually advances the bowel over the endoscope. After the bowel is telescoped onto the endoscope it is slowly withdrawn while the endoscopist examines the mucosal lumen and the surgeon watches the transilluminated bowel wall. While this technique can be effective, it is limited by its invasive nature.⁵⁹

Double Balloon Enteroscopy

This technique utilizes a long enteroscope and a long overtube. Both the overtube and the enteroscope have balloons at the end. When the balloon of the enteroscope is inflated it “grabs” the mucosal surface and allows advancement of the overtube whose balloon is deflated. The overtube balloon is then inflated while the enteroscope balloon is deflated. The enteroscope is then advanced while the inflated overtube balloon grips the mucosa. Using these alternate inflation–deflation cycles, long distance advancement of the enteroscope has been achieved.² In one U.S. multicenter study, the average distance achieved was 360 cm with a diagnosis made in 43% of cases.⁶⁰ In some cases lesions may be seen that are missed by other techniques.⁶¹

Wireless Capsule Endoscopy

Imaging of the small intestine is also possible with wireless capsule endoscopy (CE) which consists of a battery, light source, imaging-capturing system, and transmitter. This capsule endoscope is 11 × 30 mm and is moved solely by peristalsis. This system captures and sends usually two images per second (newer versions can send more frames per second) for about 8 hours to an ultra-high-frequency band radiotelemetry unit worn by the patient. In 85% of cases, the capsule reaches the cecum within this time frame.⁶² The location of the capsule is suggested by the strength of the signal. Several studies have shown high diagnostic yields using this technique and found it to be at least equivalent to and in some studies superior to double balloon enteroscopy in patients with obscure GI bleeding.⁶³ It has also been shown to have a higher diagnostic yield with comparable outcomes when compared to angiography.⁶⁴ The main risk of CE is capsule retention. One difficulty with CE is the very large amount of data to be reviewed. For an 8-hour study, 50,000 to 60,000 images are generated, which takes approximately 40 to 60 minutes to review.

Selective Visceral Arteriography

Selective visceral arteriography is primarily useful in patients with UGI or LGI bleeding in whom endoscopy cannot be performed or has been unsuccessful in determining the site of ongoing, rapid hemorrhage. Successful angiographic identification of the source of bleeding occurs in 27% to 86% of instances and depends primarily upon the presence of active arterial bleeding at the time of the study (Fig. 65-2).^{55,65} The extravasation of contrast may be detected if the patient is bleeding at rates greater than 0.5 to 1 mL/ min⁶⁶; this correlates clinically with the requirement for continuous volume infusion to maintain hemodynamic stability. Pennoyer et al.,⁶⁷ however, were unable to identify any clinical parameters (including tachycardia, numbers of transfusions, or orthostatic hypotension) that could increase the diagnostic yield of selective angiography, including scintigraphy demonstrating ongoing bleeding. However, a study by Hammond et al.⁶⁸ found an early (within 2 minutes) positive scintigraphy has a 60% positive predictive value for a positive angiogram. Additionally, it has been shown that a positive scintigram increases the likelihood of a positive angiogram from 22% to 53%.⁶⁹ Several groups have used heparin, vasodilators, or thrombolytics to improve the diagnostic yield of arteriography in patients with nondiagnostic studies.^{70,71} Mernagh et al.⁷² found that the administration of heparin intravenously for 24 hours increased the diagnostic yield of visceral angiography from 33% (6 of 18) to 67% (12 of 18). Others have found that the intra-arterial infusion of a vasodilator, heparin, and/or urokinase (a thrombolytic) failed to identify the source of bleeding in 5 of 7 patients.⁷³ It should be noted that these provocative techniques are not commonly employed.

Figure 65-2. Selective celiac arteriography with injection into the common hepatic artery in a patient bleeding from a duodenal diverticulum. Extravasation of contrast from a branch of the gastroduodenal artery can be seen (*arrow*).

One major advantage of visceral arteriography is its therapeutic potential. Transcatheter embolization of bleeding vessels was first reported in the early 1970s.^{74,75} Modern instruments allow superselective catheterization of terminal vessels allowing satisfactory embolization with less risk for ischemic complications. Further discussion of therapeutic use can be found below.

Abdominal Scintigraphy

Abdominal scintigraphy with ^{99m}Tc -labeled RBCs lacks the spatial resolution and diagnostic precision of angiography and endoscopy; however, it is of most value in detecting intermittently bleeding lesions, those with very low rates of hemorrhage such as vascular malformations, and in evaluation of LGI bleeding due to the lower sensitivity of endoscopy within the LGI tract as compared to the UGI tract. Abdominal scintigraphy utilizing ^{99m}Tc -RBCs has been shown to be the most sensitive examination due to its ability to detect bleeding rates as low as 0.04 to 0.1 mL/min.^{76,77} In a review of seven retrospective studies with nearly 400 patients, the median diagnostic accuracy of scintigraphy was 82% (range, 52% to 95%). However, in this review, ^{99m}Tc -RBCs was incorrect in 5% to 48% of instances (median 18%).⁶⁵ Suzman et al.⁷⁸ summarized 20 retrospective studies containing 804 positive studies and reported a false-positive rate of 19%. The large variation in these studies results from differences in scan timing, technical skills, and expertise. Additionally, precise localization of the site of bleeding may be complicated by the rapid distribution of isotope throughout the intestine by peristalsis or by accumulation in the right colon.⁷⁹ More recent techniques of cine scintigraphy may improve the diagnostic accuracy (Fig. 65-3).⁸⁰ One area where radionuclide scanning has a clear role is in the diagnosis of Meckel diverticulum. ^{99}Tc -pertechnetate is secreted by ectopic gastric mucosa in Meckel diverticula.⁸¹ This study should be considered early in the evaluation of young individuals with LGI bleeding.

Figure 65-3. Cine- ^{99}Tc erythrocyte scintigraphy showing extravasation of isotope in the right colon. Only a small portion of the image set is shown. Arrows point to accumulation of isotope in right colon. Bleeding was due to delayed hemorrhage following endoscopic polypectomy.

CT Scanning

CT scanning has been used to detect GI bleeding using a variety of specialized techniques.⁸²⁻⁸⁴ Multidetector-row helical computed tomography (MDCT) is establishing itself as a rapid, noninvasive, and accurate diagnostic method in acute GIB. In arterial phase MDCT, active GI bleeding is defined as active contrast extravasation with a focal area of high attenuation within the bowel lumen.⁸⁵ Yoon et al.⁸⁶ presented the first prospective study evaluating the accuracy of MDCT and found an overall sensitivity of 90.9% for the detection of acute GI bleeding and specificity of 99%. Additional studies have supported its use.^{87,88} Limitation of MDCTs are radiation dose, contrast allergies, contrast nephropathy, and it being a purely diagnostic rather than therapeutic modality. However, it is fast, accurate, widely available, reproducible, noninvasive, and a positive study can subsequently guide interventionalists to directly perform time-saving super-selective angiograms of the bleeding site.⁸⁵ In the future this may continue to become a more available and useful technique.

COMMON CAUSES OF GI HEMORRHAGE AND TREATMENT

Upper GI Hemorrhage

Peptic Ulcer Disease

Peptic ulcer disease is the most common cause of acute UGI hemorrhage, accounting for nearly 40% of cases in most series although this proportion may be decreasing.⁸⁹ About 15% to 20% of patients with peptic ulcer disease experience bleeding during the course of their disease and as many as 20% of these patients will have bleeding as the initial manifestation. Hemorrhage is the principal cause of death from peptic ulcer disease and has replaced intractable pain as the most frequent indication for surgery. Complications of peptic ulcer disease occur more commonly in older patients who often have coexisting medical problems, which profoundly influence their risk of morbidity and mortality.

Duodenal ulcers occur slightly more frequently than gastric ulcers. Penetration of the ulcer through the posterior wall of the duodenal bulb is associated with erosion into the gastroduodenal artery or one of its branches, resulting in brisk hemorrhage. Patients may present with hematemesis of bright red blood and clots or with melena alone. Between 80% and 90% of patients stop bleeding spontaneously during the initial stages of therapy with volume resuscitation.

In general, patients with gastric ulcers tend to be older and have coexisting medical problems that increase morbidity and mortality compared with duodenal ulcers. Bleeding may occur from any site in the stomach, although ulcers occurring at the incisura are most common. At this site, involvement of the branches of the left gastric artery may result in brisk, if not torrential, hemorrhage. The clinical presentation of patients bleeding from gastric ulcers is similar to that of duodenal ulcers, with hematemesis, melena, and hematochezia.

6 An important risk factor for the development of GI hemorrhage and gastroduodenal ulcer formation is the use of NSAIDs. NSAID use has been associated with a continuum of mucosal injury ranging from small acute mucosal hemorrhages to large chronic ulcers. It has been estimated that 10% to 15% of regular NSAID users have chronic gastric ulcers.⁹⁰ Symptoms correlate poorly with the degree of mucosal injury since as many as 20% of ulcers penetrating the muscularis are asymptomatic.⁹¹ Case control and cohort studies have suggested that NSAIDs are associated with a relative risk of GI hemorrhage and ulceration ranging from about 2 to 9.1.⁹² Ketorolac, in particular, has been associated with a high risk of GI bleeding (relative risk approaches 25).⁹³ The risk of NSAID-associated complications is highest in patients with a history of UGI bleeding, the elderly, those patients taking oral anticoagulants,⁹⁴ or corticosteroids. Patients with a prior history of peptic ulcer disease also appear to be at increased risk of NSAID-associated GI hemorrhage and tend to have a significantly worse outcome when compared to individuals not using NSAIDs.⁹⁵

The tremendous frequency with which NSAIDs are used by the elderly underscores the magnitude of this problem. Individuals with a history of NSAID-induced hemorrhage may benefit from the prostaglandin E₁ analog, misoprostol, which has been shown to prevent NSAID-induced gastric erosions and ulcers.⁹⁶ Histamine (H₂)-receptor blockers (ranitidine and cimetidine) are effective in preventing NSAID-induced duodenal ulcers, but appear to have little effect on the occurrence of gastric lesions.^{91,97} Proton pump inhibitors (PPIs) have also been shown to be protective in patients on NSAIDs, with greater efficacy than H₂ blockers.⁹⁸ NSAIDs are also associated with lower GI bleeding, including lesions not generally considered related to NSAID-induced ulcers such as diverticulosis.^{99,100} Selective COX-2 inhibitors have been marketed as being safer than nonselective NSAIDs, although some of these have been withdrawn from the U.S. market for other safety concerns. It appears that these selective inhibitors cause fewer UGI problems overall than traditional NSAIDs, the main benefit being fewer uncomplicated ulcers. Various studies have shown no decrease in complicated events, including clinically significant bleeding episodes.^{101,102} However, in a Cochrane systematic review of the GI safety of COX-2 inhibitors, COX-2 inhibitors produced significantly fewer gastroduodenal ulcers (relative risk, 0.26; 95% CI = 0.23–0.30) and ulcer complications (relative risk, 0.39; 95% CI = 0.31–0.50), as well as fewer withdrawals caused by GI symptoms when compared to nonselective NSAIDs.¹⁰³

Medical Treatment

7 Once bleeding from the UGI tract is confirmed, treatment with a PPI should be initiated. Acute use of a PPI has been shown in several studies to decrease rebleeding.^{43,104–107} Although the Scottish Intercollegiate Guidelines Network (SIGN) recommended withholding PPI therapy until after endoscopy,^{108,109} in our opinion the balance of evidence would suggest no harm and perhaps a benefit

from early PPI use. An 80-mg intravenous bolus of omeprazole or pantoprazole followed by an infusion at 8 mg/hr produces the most reliable acid suppression.¹¹⁰ All patients should be tested for *Helicobacter pylori* (*H. pylori*) infection and treated if found. Treatment of the infection significantly reduces the recurrence of hemorrhage when compared to no treatment or chronic antisecretory treatment alone.¹¹¹ Interestingly *H. pylori* infection may be less common in patients with bleeding ulcers than in those with nonbleeding ulcers.¹¹²

Endoscopic Treatment

The endoscopic appearance of a bleeding ulcer has important prognostic and therefore therapeutic implications, as alluded to in Tables 65-6 and 65-7. A modification of the system employed by Forrest et al.¹¹³ is shown in Table 65-8. In this system, category I findings are indicative of active bleeding while category II findings provide evidence of recent hemorrhage. In general, only actively bleeding ulcers (i.e., Forrest category I lesions) are treated endoscopically.

Table 65-8 Forrest Classification of Endoscopic Appearance of Bleeding Ulcers

Ia	Spurting bleeding
Ib	Nonspurting, active bleeding
IIa	Visible vessel
IIb	Nonbleeding ulcer with overlying clot
IIc	Ulcer with hematin-covered (black) base
III	Clean ulcer base

From Yamaguchi T, Yoshikawa K. Enhanced CT for initial localization of active lower gastrointestinal bleeding. *Abdom Imaging* 2003;28:634–636.

A variety of endoscopic techniques are available to arrest hemorrhage from bleeding ulcers. The precise method of treatment is less important than the correct selection of patients and the experience of the endoscopist. Examples of methods typically include mechanical, thermal, or injection.

Mechanical ligation of bleeding vessels can be achieved with endoscopic ligation (banding), endoscopic clipping, or endoloop ligation.^{114–116} Of these three methods, endoscopic clipping is the method most commonly employed for bleeding ulcers.

Heater probes and monopolar and bipolar electrocoagulation probes can also effectively control UGI hemorrhage. Monopolar probes apply high-frequency electrical current to the tissue, resulting in localized heating to 100°C and sealing of the bleeding vessel by coagulation necrosis of the surrounding tissue and vessel wall. Multipolar electrocoagulation (bicap) probes consist of three equally spaced pairs of bipolar microelectrodes. This orientation of electrodes allows coagulation of tissue from tangential approaches and eliminates some of the disadvantages of the monopolar probe, such as the unpredictable depth of thermal injury, adherence of tissue, and clot dislodgement. Direct thermal coagulation of a bleeding point can also be produced by applying a heater probe, consisting of an aluminum tip coated with Teflon. The tip is rapidly heated to 250°C by an inner coil. The tip can be irrigated with a water jet to prevent accumulation of debris and clot. Heat conducted from the probe produces tissue coagulation to a depth of 1 to 5 mm.

Injection of epinephrine to induce vasoconstriction has been used successfully to control acutely bleeding ulcers, particularly as an adjunct to electrocautery or mechanical hemostasis with clips. A meta-analysis of 15 studies concluded that injection alone was inferior to either clips alone, or clips plus injection.¹¹⁷ This study showed no difference between clips and thermocoagulation.

Although not commonly employed, the injection of sclerosants has been well described as a method of treating esophageal varices and has been used for controlling nonvariceal bleeding. Sodium morrhuate and ethanolamine oleate are most commonly used to treat esophageal varices, whereas ethanol and polidocanol are most commonly used for nonvariceal sites. These agents act by thrombosing bleeding vessels and causing necrosis and subsequent fibrosis of surrounding tissue. Clinical experience with sclerosants has been similar to that obtained with electrocoagulation. In one large multicenter study of 332 actively bleeding patients or patients with stigmata of recent hemorrhage who underwent injection of 98% alcohol around the lesions, less than 1% continued to bleed, 6% rebled, and only 3% required emergency operative intervention.¹¹⁸

A meta-analysis of 25 randomized trials of endoscopic therapy for bleeding ulcers concluded that endoscopic treatment methods have a beneficial effect on survival by reducing the rate of recurrent hemorrhage. This analysis suggested that endoscopic therapy results in a relative reduction of 69% in

recurrent bleeding, 62% in emergent surgery, and 30% in mortality rate, with the greatest benefit seen in actively bleeding ulcers and ulcers with nonbleeding visible vessels.¹¹⁹ The effectiveness of early aggressive endoscopic diagnosis and treatment is further supported by a report of 562 patients bleeding from a variety of causes of whom only 2.5% required emergency operations to control hemorrhage.¹²⁰ Several other more recent studies have confirmed the critical role of endoscopy and control of UGI hemorrhage.^{43,121,122} For most patients with evidence of persistent bleeding, a second attempt at endoscopic hemostasis should be attempted because this can provide up to 75% of patients with durable hemostasis. Exceptions may include patients with ulcers greater than 2 cm in diameter and those who have hypotension associated with a rebleeding episode, since such patients may be at an increased risk for failure of repeat endoscopic hemostasis.^{104,121,123}

Operative Treatment

The successful use of endoscopic therapies has relegated operative procedures to a rescue role for those cases in which endoscopy is unsuccessful in arresting hemorrhage. Numerous studies have attempted to identify those patients at greatest risk of continued or recurrent bleeding. Of the many factors examined, those associated with the highest risk of rebleeding included patients in hypovolemic shock during the initial endoscopy, ulcers greater than 2 cm in diameter, and endoscopic stigmata of recent or ongoing hemorrhage (Forrest type I and II lesions).¹²³ Many studies have demonstrated the ability of endoscopy to identify those patients at greatest risk of rebleeding. In one review, the presence of active bleeding was associated with a 90% to 100% chance of continued or recurrent hemorrhage. A nonbleeding visible vessel had a 40% to 50% chance, adherent clot 20% to 30%, oozing without visible vessel 10%, flat spot 5% to 10%, and clean-based ulcer 1% to 2%.¹²⁴ Even in those patients who rebleed following initial endoscopic therapy, two-thirds may be successfully retreated endoscopically thus avoiding operative intervention.⁹⁰ Factors that must be considered in decisions regarding the timing of operative intervention include the magnitude of the initial (or recurrent) hemorrhage, the physiologic ability of the patient to withstand continued or recurrent hemorrhage, and the likelihood of recurrent or continued hemorrhage. It is generally accepted that elderly patients and those with significant concurrent medical problems should undergo operative intervention earlier during the course of the hemorrhage since these individuals will poorly tolerate continued bleeding, recurrent hypotension, and repeated transfusions.

The type of operation depends on the pathology encountered. For bleeding gastric ulcers, the operation of choice depends on the patient's condition and location of the ulcer. For favorably located ulcers, excision of the ulcer with closure of the gastrotomy will suffice. If the ulcer is unfavorably located, for example, near the gastroesophageal junction, simple oversewing of the vessel through the base of the ulcer may adequately control bleeding.¹²⁵ If a gastric ulcer is left in situ, follow-up endoscopy is necessary 4 to 8 weeks later to either confirm healing or obtain tissue to rule out malignancy. Extensive gastric resections such as antrectomy, subtotal or total gastrectomy are generally not performed in these unstable patients.

For patients bleeding from duodenal ulcers, the type of surgery performed has changed since the development of PPIs and treatment of *H. pylori*. Formerly, truncal vagotomy, pyloroplasty, and oversewing of the bleeding vessel were the most widely used operation. However, the trend is now more toward direct ligation of the bleeding vessel through the duodenotomy.¹²⁶ When performed, ligation should incorporate the gastroduodenal artery proximal and distal to the ulcer as well as the transverse pancreatic artery. Despite the above noted trend, a recent study has shown vagotomy and drainage may be superior to simple oversewing of the vessel.¹²⁷

Angiographic Embolization

Of late, much has been written about the use of transcatheter embolization for peptic ulcer disease. In general, angiographic embolization is used after failure of endoscopic treatment in patients who cannot or will not undergo surgery. One large review (including nonulcer UGI indications) showed a high technical success rate (i.e., localization of bleeding and deployment of the embolic agent) but a clinical success rate of only 51%.¹²⁸ Other reviews have shown higher success rates ranging from 69% to 100% technical success rate and 63% to 97% clinical success rate.¹²⁹ Significant ischemic complications can occur however. While this technique has utility in select patients, it should not be considered as a first-line treatment option for bleeding peptic ulcers, but may have a role as a safe alternative to surgery for ulcers refractory to endoscopic treatment.

Stress Gastritis

Although studies in the 1960s and 1970s demonstrated acute erosions of the gastric mucosa in as many as 60% to 100% of critically ill patients, the incidence has markedly decreased over the past four decades. Factors postulated to have been important in this phenomenon include (1) the widespread use of prophylactic gastric alkalization; (2) improvements in the ability to detect and treat sepsis; (3) improvements in the ability to monitor and correct hemodynamic instability; and (4) the ability to provide adequate nutritional support of critically ill patients.

In general, stress gastritis is characterized by the appearance of multiple superficial gastric ulcerations within 12 to 14 hours of an acute injury. These lesions, initially localized to the fundus and body of the stomach, later involve the entire gastric surface. Patients at greatest risk include those with sepsis, major burns, severe trauma, and critically ill patients with a coagulopathy and respiratory insufficiency.¹³⁰ In this setting, the disease appears to represent the gastric component of the multiorgan failure syndrome.

The pathogenesis of this disease is discussed in detail in [Chapter 45](#). The primary defect is in the protective processes that maintain the integrity of the gastric mucosal barrier. Although some gastric acid secretion is required for the development of stress gastritis, it is clear that the hypersecretion of acid is not the cause of mucosal injury. Altered gastric mucosal blood flow and impaired clearance of hydrogen ions from the mucosa appear to be of particular importance; therefore, the best method of prevention of stress gastritis is to prevent gastric ischemia and acid injury. Stress gastritis should be differentiated from the deep, often solitary ulcerations occurring in patients with severe central nervous system lesions (Cushing ulcers).

Generally hemorrhage is the only symptom that patients with stress gastritis experience. Overt bleeding is often heralded by the appearance of flecks of blood in the gastric aspirate. The superficial nature of the lesions makes perforation unlikely.

Prophylactic therapy is directed toward preventing hemorrhage, primarily by neutralizing gastric acid, augmenting mucosal defenses, and removing or preventing physiologic stress. The gastric pH should be maintained between 3.5 and 4.5.¹³¹ Antacids, H₂-receptor antagonists, PPIs, and sucralfate have all been used to prevent stress gastritis. Alkalinization of the gastric contents is associated with oral and fecal flora colonization of the stomach and has raised concerns about an increased risk of nosocomial pneumonia. This concern prompted the use of sucralfate as a preferred prophylactic agent for some time instead of antacids or cimetidine.¹³² However, a prospective, randomized trial of 1,200 critically ill patients receiving either ranitidine or sucralfate for stress ulcer prophylaxis found that those patients receiving ranitidine had a lower bleeding rate (1.7%) than the sucralfate group (3.8%) but there was no difference in mortality or incidence of ventilator-assisted pneumonia.¹³³ Since that time, studies have shown PPIs to be a safe and effective method of stress prophylaxis, but the number of studies with high-quality data is still lacking.

The success of these prophylactic measures has led to a dearth of recent experience in managing patients bleeding from stress gastritis. Based on early reports, attention to blood replacement, intravascular volume restoration, and correction of coagulation defects are associated with the cessation of hemorrhage in nearly 80% of cases and as such are the principal means of initial treatment. A variety of nonoperative techniques have been employed with variable success in arresting hemorrhage from stress gastritis including endoscopic and embolization techniques and the selective catheterization of the left gastric artery with continuous infusion of vasopressin.¹³⁴

Based on these same early experiences, very few patients bleeding from erosive gastritis require operative intervention to arrest hemorrhage. A variety of surgical treatment options have been reported including vagotomy and pyloroplasty with oversewing of bleeding sites, vagotomy and hemigastrectomy, total gastrectomy, and gastric devascularization. The dilemma facing the surgeon is that these critically ill patients poorly tolerate extensive procedures, yet lesser operations often fail to control hemorrhage. Regardless of the operation performed, mortality risk depends on the underlying illness, particularly in the presence of multiple organ failure. Mortality rates between 30% and 60% are commonly quoted, with as many as one-fourth of the deaths resulting from continued hemorrhage. Rebleeding rates ranging from 25% to 61% have been reported. The combination of vagotomy, hemigastrectomy, and oversewing of bleeding points has been touted as more successful in these patients; however, rebleeding rates of 11% to 44% and operative mortality rates ranging from 33% to 63% have been associated with this procedure.¹³⁵ More extensive operations, such as near total gastrectomy or total gastrectomy are associated with significant mortality although they successfully stop hemorrhage.

Gastroesophageal Varices

Cirrhosis is a leading cause of death in the United States and variceal hemorrhage is a common mode of death for these patients. About 30% of people with cirrhosis develop gastroesophageal varices; of these individuals, about 30% bleed as a result of the varices, usually within 1 to 2 years of diagnosis. Gastroesophageal varices are a significant cause of UGI hemorrhage, accounting for about 20% of such cases. Patients with bleeding gastroesophageal varices tend to have much higher rebleeding rates, transfusion requirements, lengths of hospitalization, and risk of death than do patients bleeding from nonvariceal causes.^{120,136}

Although the basic tenets of resuscitation for massive variceal hemorrhage are similar to those for any cause of massive bleeding, intravenous volume resuscitation should be particularly judicious. The hyperaldosteronemic state of cirrhosis promotes sodium and water retention with aggravation of ascites and peripheral edema. Accurate blood replacement is imperative since overtransfusion may worsen portal hypertension and exacerbate hemorrhage. Invasive cardiac monitoring with Swan–Ganz catheterization may be particularly useful for guiding volume replacement. Coagulation deficits should be aggressively corrected by administering fresh frozen plasma. Thrombocytopenia, secondary to hypersplenism or dilution, should be treated promptly with pooled platelet transfusions. Sedatives are best avoided or used sparingly because cirrhosis impairs the liver's ability to metabolize many of these drugs. Adequate prophylaxis for delirium tremens should be administered to alcoholics.

As with other sources of UGI hemorrhage, early endoscopy is imperative for successful diagnosis and therapy.¹³⁷ The identification of varices alone is not adequate to incriminate them as the source of the hemorrhage since up to half of patients with cirrhosis bleed from a source other than varices. Furthermore, endoscopy may identify factors associated with a heightened risk of variceal hemorrhage such as the size and number of varices and the presence of red, blue, or other colored spots on the varix. The presence of gastric and duodenal varices and portal hypertensive changes in the gastric mucosa (portal gastropathy) will influence therapeutic decisions and prognosis.

Although vasopressin has commonly been used in the management of variceal hemorrhage, its use has been limited due to the potent vasoconstrictive properties causing cardiac and peripheral ischemia, arrhythmias, hypertension, and bowel ischemia. More recent reports suggest the superiority of somatostatin or its synthetic analog, octreotide. It is thought that octreotide causes splanchnic arteriolar vasoconstriction and reduces variceal and azygous vein flow with limited direct effects on portal pressure.¹³⁸ Meta-analyses have shown that the infusion of somatostatin is more effective and safer than vasopressin in the pharmacologic control of variceal hemorrhage.^{139,140} Other studies have shown that somatostatin or octreotide can improve the results of sclerotherapy or endoscopic variceal ligation.^{141,142} Although neither somatostatin nor vasopressin plus nitroglycerin definitively treat the bleeding esophageal varices, these modalities may provide initial control of hemorrhage, reducing transfusion requirements and providing time for resuscitation before definitive treatment.

Another temporizing method used for massively bleeding patients is balloon tamponade using a Sengstaken–Blakemore tube or a Minnesota tube. These devices consist of a gastric tube with esophageal and gastric balloons. In the case of a Minnesota tube, a proximal esophageal lumen allows for the aspiration of swallowed secretions. Inflation of the gastric (and if required esophageal) balloons tamponade the bleeding varices, controlling hemorrhage in more than 80% of cases. Hemorrhage recurs in 25% to 50% of patients upon deflation of the balloons, thus limiting this technique to a temporizing role.¹⁴³ The greatest value of these tubes is for arresting massive hemorrhage that has been unresponsive to other measures, allowing time for resuscitation and angiographic definition of the portal system before definitive treatment.

When used inappropriately, these tubes can be associated with significant morbidity and mortality. Complications occur in 4% to 9% of patients with the most frequent being aspiration pneumonitis. Measures to prevent pulmonary complications include endotracheal intubation before tube insertion and the placement of an esophageal tube to remove swallowed salivary secretions. Other significant complications include esophageal rupture or necrosis and airway occlusion during the attempted removal of an incompletely deflated gastric balloon. Because of the availability of endoscopy, these tubes are rarely used today.

8 Endoscopic sclerotherapy, endoscopic clipping or endoscopic variceal ligation (banding) have become the most widely used modalities for the initial definitive control of bleeding esophageal varices. Several studies have confirmed that these techniques arrest acute variceal hemorrhage in 90% to 95% of patients. In general, a patient bleeding from esophageal varices should undergo urgent pharmacologic therapy and banding of the varices at the time of the first emergency endoscopy. Sclerotherapy can be used if ligation is technically difficult.¹³⁷ A single endoscopic treatment controls variceal bleeding in

more than 70% of patients, and a second treatment increases the rate of control from 90% to 95%. Continued or recurrent hemorrhage after endoscopic treatment often requires emergency portal decompression either with transjugular intrahepatic portosystemic shunting (TIPS) or rarely surgery.^{144–146} Following an initial episode of variceal hemorrhage several options are available for the prevention of further hemorrhage. These options, as well as the operative management of bleeding esophageal varices are discussed in detail in [Chapter 59](#).

Mallory–Weiss Tears

The Mallory–Weiss syndrome is acute UGI hemorrhage that occurs after retching or vomiting. Mallory and Weiss described the laceration of the gastric cardia and postulated that violent emesis against an unrelaxed cardia was the mechanism of injury. They were able to produce similar mucosal tears in cadavers by forcing gastric contents against an occluded gastroesophageal junction.¹⁴⁷ The typical patient is an alcoholic who begins to retch and vomit after an alcohol binge although this syndrome may also be found in nonalcoholics with bouts of emesis. Initially the vomitus consists of gastric contents without blood and subsequently the patient develops hematemesis and/or melena. Overall, these lesions account for about 5% to 10% of patients with UGI bleeding.^{120,136,148}

The initial management of these patients is similar to that of patients bleeding from other sources of UGI hemorrhage and includes volume resuscitation, gastric lavage, and decompression. Most patients with Mallory–Weiss tears stop bleeding spontaneously, either before treatment or after these early measures. Once bleeding has stopped, rebleeding is rare.

In patients who continue to bleed despite these maneuvers, nonoperative and operative therapeutic options are available. Nonoperative management, consisting of endoscopic electrocoagulation, banding or injection therapy, has been successfully applied to these lesions.¹⁴⁹ In cases not amenable to endoscopic therapy, operative management consists of oversewing the laceration through an anterior longitudinal gastrotomy in the middle third of the stomach.

LOWER GI HEMORRHAGE

Although the passage of maroon or bright red blood per rectum may occur in the presence of a massive UGI hemorrhage, this finding most commonly indicates a source distal to the ligament of Treitz. The absence of blood in bilious nasogastric lavage further supports a distal location of hemorrhage. Although numerous potential causes of LGI hemorrhage are possible ([Table 65-2](#)), colonic diverticulosis and colitis are by far the most common. Small bowel sources and other colonic pathology such as colon cancer are relatively unusual causes of acute GI hemorrhage.

Diagnostic Approach

The most important question to answer when presented with a patient with LGI hemorrhage is not, “What is bleeding?” but rather, “Where is the bleeding?” The common causes of colonic hemorrhage are mucosal in nature, not palpable, and not visible from the serosal surface of the bowel. Therefore, it is imperative that the surgeon makes every effort to localize the source of bleeding preoperatively since it is usually impossible to locate intraoperatively. If the surgeon waits to attempt localization until it is clear that surgical treatment will be required it may be too late. Colonoscopy, tagged RBC scanning and/or angiography should be obtained as early as possible after presentation.

After determination that the bleeding is likely from an LGI source, it is important to first exclude anorectal causes of hemorrhage, such as hemorrhoidal bleeding. At this point, colonoscopy is usually performed as it can rule out anorectal causes of bleeding, but also help determine non-anorectal causes of hemorrhage. In the authors’ experience, despite studies showing high value, colonoscopy in an actively bleeding patient with an unprepped colon is seldom therapeutic. However, it can be of significant diagnostic benefit. It is usually fairly easy to determine when bleeding is from a neoplasm, and noting the location helps guide the surgeon in decision making. Conversely in AVMs and diverticular bleeding, locating the actual source of bleeding is often unsuccessful due to the presence of blood and stool. However, noting the extent of blood in the colon can be helpful to guide future surgical decision making. For example, if blood is only noted in the sigmoid colon and rectum, this suggests bleeding is from a distal source and a sigmoid colectomy may suffice if bleeding persists. Alternatively if blood is noted throughout the entire colon, the location of the bleed is unclear and a total colectomy may be necessary. The terminal ileum should be intubated as well. While a small amount of blood can

reflux into the terminal ileum, if an extensive amount of blood is noted then a small bowel source should be considered and the surgeon should be hesitant about performing a total colectomy if bleeding persists.

Alternatively, a tagged RBC scan can be obtained as soon as practical, or in occasional cases of massive hemorrhage, conventional angiography or MDCT. If the tagged RBC scan localizes a bleeding site, the patient is then sent for angiography to attempt to embolize the bleeding vessel. If the tagged RBC scan does not demonstrate bleeding, then it is probable that bleeding has stopped. One may then proceed to colonoscopy after adequate mechanical bowel preparation.

If the bleeding is rapid enough to warrant emergency surgery, bleeding can usually be demonstrated by tagged RBC scan, MDCT, or angiography. It should be the very rare patient who will need to proceed to surgery for LGI hemorrhage with failed preoperative localization. In these cases a careful search for small bowel bleeding sources, possibly including intraoperative small bowel endoscopy, should be performed.

Colonic Diverticulosis

9 In Western society, the prevalence of colonic diverticula increases with age such that about 60% of people in their seventh decade of life are affected and the incidence increases roughly 1% per year. Only about 20% of patients with diverticulosis have symptoms attributable to these lesions and less than 5% experience hemorrhage.¹⁵⁰ Hemorrhage from diverticular disease is most often massive, associated with hematochezia, and accompanied by varying degrees of hemorrhagic shock. Classically, patients present with a sudden occurrence of mild lower abdominal discomfort, rectal urgency, and the subsequent passage of a large bloody stool. Because the colon can contain large volumes of blood, neither the volume nor the frequency of bloody stools is a reliable guide to the rate of hemorrhage. Despite the massive nature of hemorrhage, most patients with diverticular disease stop bleeding spontaneously. Most series report bleeding ceases spontaneously in 80% of cases, although up to 25% to 50% can rebleed. Of those who rebled, less than one-fourth required surgery.¹⁵¹

Bleeding associated with diverticular disease comes from a perforated vasa recta located at the neck or apex of a diverticulum. The vasa recta penetrates the colonic wall from the serosa to the submucosa through obliquely oriented connective tissue septa. Protrusion of colonic mucosa through this connective tissue plane causes apposition of the diverticulum and the vasa recta (Fig. 65-4). Ulceration of the mucosa within the neck of the diverticulum and disruption of the arterial wall produces hemorrhage into the lumen of the bowel. Although diverticular disease is more prevalent in the left colon, right-sided lesions account for half or more episodes of bleeding.^{151,152} Risk factors for rebleeding are hypertension, NSAID use, coagulopathy, renal failure, ischemic heart disease, and cluster type diverticula.^{153,154}

Figure 65-4. Colonoscopic view of a colonic diverticulum. A vasa rectum is seen entering the diverticulum and forming one of the walls.

The massive nature of the bleeding caused by colonic diverticula limits the diagnostic usefulness of

colonoscopy. Rarely is a bleeding vessel seen within a diverticulum and the presence of blood or clot within a diverticulum is of no diagnostic benefit. Selective mesenteric arteriography may demonstrate the luminal extravasation of contrast; however, in one study of patients bleeding from diverticulosis, angiographic localization was effective in less than 20% of patients.¹⁵⁵ Failure to visualize a bleeding point is usually due to cessation of active bleeding at the time of angiography.

Given the relatively low risk of recurrent hemorrhage, patients who stop bleeding should be treated expectantly. About 10% of patients bleeding from colonic diverticula continue to bleed and ultimately require operative intervention. Embolization of bleeding vessels in the colon has been reported to be safe and effective in the majority of patients; however there is a definite risk of ischemic complications.^{156,157} The rapid nature of the hemorrhage and the difficulty in defining the site of bleeding through the endoscope can limit endoscopic attempts at control of diverticular hemorrhage, especially in patients with large volume rapid bleeding.

If the site of bleeding can be localized, patients who continue to bleed from diverticular disease should undergo resection of the colon segment that contains the site of bleeding. Even after successful localization of a bleeding source, the least operation that can usually be contemplated is a hemicolectomy or wide segmental colectomy. Segmental colon resection has been associated with rebleeding rates of only 0% to 15% and mortality rates of 0% to 13%. Tagged RBC scanning, while sensitive, cannot always pinpoint a bleeding site with great accuracy. Although angiography usually gives more precise localization, correlation between the vascular pattern and the anatomic location is sufficiently imprecise to warrant at least a segmental resection. Finally, measurement with colonoscopy is notoriously misleading with even experienced endoscopists making mistakes about the precise site of a lesion. If the location is unable to be localized and the blood appears confined to the colon, a total abdominal colectomy should be performed as most studies show rebleeding rates of 0%, and “blind” segmental colectomy has been shown to have a rebleeding rate of up to 75%.⁶⁵ However, the surgeon and patient should be aware of a failure rate even after total abdominal colectomy as the small bowel could potentially be the source. There are few worse sights for the surgeon than blood coming from an ileostomy after a blind total abdominal colectomy for bleeding.

Although a total colectomy, often with end ileostomy, for nonlocalized ongoing colonic hemorrhage may occasionally be necessary, it should be performed only after exhaustive attempts to localize the site of bleeding. Total colectomy is associated with greater perioperative morbidity rates than segmental resection and postoperative volume losses from ileostomies or diarrhea may present a significant problem to elderly patients.

Colonic Angiodysplasia

Sometimes called vascular ectasias or arteriovenous malformations, these lesions are believed to arise from the age-related degeneration of previously normal intestinal submucosal veins and overlying mucosal capillaries. Angiodysplasia is located most frequently in the cecum and ascending colon, although it may be found more distally in 20% to 30% of cases. Multiple lesions may be present in as many as 40% to 75% of all cases.¹⁵⁸ Microscopically, angiodysplasia consists of dilated, thin-walled vessels that appear to be ectatic veins and venules localized within the submucosa. A dilated submucosal vein is often found and occasionally an enlarged artery. Angiodysplasia is generally thought to be an acquired lesion associated with aging, but the exact etiology is unknown.

The prevalence of colonic angiodysplasia in the general population appears to be less than 1%.¹⁵⁹ These lesions may present with hematochezia, melena, occult blood loss, or iron-deficiency anemia. Bleeding lesions are most commonly found in the right colon. As compared to diverticular bleeding, episodes of hemorrhage from vascular ectasias are usually less severe, and are somewhat more likely to recur. After the initial episode of hemorrhage, the majority of patients will stop bleeding spontaneously.¹⁶⁰

Vascular ectasias may be diagnosed by either colonoscopy or by selective mesenteric angiography. Colonoscopy has been reported to have a sensitivity of 80% in demonstrating vascular ectasias.¹⁶¹ However, colonoscopic diagnosis of these lesions in actively bleeding patients may be confounded by the presence of other incidental lesions including traumatic and suction artifacts produced during the examination. In addition, after significant bleeding and hypovolemia, the shunting of blood flow away from the intestinal mucosa may obscure these lesions in inadequately resuscitated patients. When vascular ectasias are located, colonoscopy can be used effectively to treat vascular ectasias either by coagulation or possibly injection of sclerosants.^{162,163}

Selective mesenteric angiography may also demonstrate these lesions and compliment colonoscopy,

particularly in patients who are massively bleeding or in whom colonoscopy was unrevealing or incomplete. Characteristic angiographic findings include a densely opacified and slowly emptying, dilated, tortuous vein (found in 90% of patients), a vascular tuft (seen in 66% to 75% of patients), and an early-filling vein (usually a segmental vein in the cecum or right colon, although at times, it may be the ileocolic vein).

The natural history of these lesions was revealed by the clinical course of 101 patients with colonic vascular ectasias.¹⁶¹ Of the 15 asymptomatic individuals without a history of bleeding, none bled during a period of follow-up to 68 months (mean, 23 months). For 31 patients with overt bleeding or anemia who were treated only with blood transfusion, the rebleeding rates at 1 and 3 years were 26% and 46%, respectively. This study suggests that the risk of bleeding for incidentally discovered lesions is minimal and empiric therapy is not warranted. However, the risk of recurrent hemorrhage for most symptomatic patients is substantial and may increase with time.

Medical treatment of vascular ectasias has been used although there is currently no proven effective medical therapy. Hormone treatment using high-dose estrogens and progesterone has been used since the 1950s but convincing proof of efficacy is lacking. Indeed, most evidence would suggest no antibleeding effect of hormonal treatment.¹⁶⁴ More recently the antiangiogenic drug thalidomide, hormones, and octreotide have been suggested as treatment options but data are lacking.^{165–167}

Endoscopic therapy has, however, proved to be more effective. Nonrandomized investigations with vascular ectasias managed with monopolar electrocoagulation, endoscopic injection sclerotherapy, contact probes, and lasers have been published with good results. All methods appear to be effective for treating bleeding vascular ectasias and all are associated with procedure-related morbidity rates of 2% to 10%. Perforation has been reported in all of these experiences with rates of 2% to 3%.

Patients bleeding from vascular ectasias in whom endoscopic hemostatic methods are unsuccessful or unavailable can be treated with resection of the colon following preoperative localization of the bleeding site. For the usual patient bleeding from a vascular ectasia in the cecum or ascending colon, a right colectomy with ileotransverse colostomy is the treatment of choice. The value of preoperative localization of the bleeding site cannot be overstated, and every effort should be made to determine the site of hemorrhage prior to laparotomy.

Ischemic Colitis

Ischemic colitis is a common cause of LGI hemorrhage especially in the elderly. Bleeding is a common presenting manifestation of ischemic colitis occurring in approximately one-half to three-fourths of patients but is usually not massive.^{168,169} Although ischemic colitis may occur with occlusion of a major artery (such as ligation of the inferior mesenteric artery during abdominal aortic aneurysm repair), in most cases it results from impaired local microvascular perfusion of the colonic wall. It occurs most commonly in the elderly who often have significant medical comorbidities. Renal failure requiring hemodialysis, hypertension, cardiovascular disease, vasoactive medications, and a variety of other risk factors have been associated with the disease.¹⁷⁰ In many cases a specific initiating event cannot be identified. Any segment of the colon may be involved. Profound ischemia may lead to full-thickness necrosis, peritonitis, and perforation. Lesser degrees of ischemia may result in vague mild to moderate abdominal pain (helping differentiate it from diverticulosis), diarrhea, and mild to moderate bleeding. Life-threatening hemorrhage is uncommon.

Ischemic colitis can be diagnosed with colonoscopy in which case the mucosa may vary from edematous to hemorrhagic and necrotic. Rarely is angiography helpful in these cases as it rarely demonstrates major vessel occlusion.¹⁶⁹ Most patients will recover uneventfully with supportive care alone. When operative management is required it is often necessitated by peritonitis or other signs of full-thickness necrosis. In these critically ill patients the mortality rate is relatively high due to the critical nature of these patients' pre-existing comorbid conditions.

UNUSUAL CAUSES OF ACUTE GASTROINTESTINAL HEMORRHAGE

As outlined in [Tables 65-1](#) and [65-2](#), a wide variety of other pathologic processes may present with acute GI hemorrhage. Although these lesions generally comprise a relatively small percentage of the total number of cases of overt GI hemorrhage, they can present vexing problems to the clinician faced with a bleeding patient in whom the usual etiologies have been excluded. There are a number of case reports in the literature of extremely rare causes of GI bleeding that will not be discussed here. The

following lesions occur commonly enough that clinicians are likely to encounter them in their practice.

Dieulafoy Vascular Malformation

Dieulafoy vascular malformation is an unusual cause of recurrent hematemesis, in which bleeding originates from an unusually large (1- to 3-mm diameter) artery running through the gastric submucosa for variable distances. Erosion of the gastric mucosa overlying the vessel results in necrosis of the arterial wall and brisk hemorrhage. The size of the mucosal defect is usually small (2 to 5 mm) and without evidence of chronic inflammation. These lesions may rarely occur in other anatomic locations of these lesions such as the colon.¹⁷¹⁻¹⁷³

Painless hematemesis and melena are typical. Recurrent bleeding with spontaneous cessation is also common. In a collective review of 101 cases, the mean age of the patients was 52 years, and the lesion occurred twice as frequently in men as women. There was no significant association with alcohol abuse or antecedent symptoms.¹⁷⁴

The diagnosis is most frequently made endoscopically by demonstrating arterial bleeding from a pinpoint mucosal defect. Occasionally, a small arterial vessel may be seen protruding from the gastric mucosa. Characteristically, the lesions are located within 6 cm of the esophagogastric junction along the lesser curvature although they may occur in other sites as well.

Most patients can be managed endoscopically by injection of epinephrine, sclerotherapy, banding, clipping or coagulation.^{175,176} A subset of patients will require retreatment or surgical excision for control of hemorrhage. After cessation of hemorrhage few patients rebleed from these lesions even when treated only by endoscopic methods.¹⁷⁷

Gastric Antral Vascular Ectasia

Sometimes abbreviated as GAVE syndrome, this entity is also known as “Watermelon Stomach” because of its characteristic endoscopic appearance. Longitudinal erosions are seen in the antrum radiating from the pylorus. It usually causes chronic blood loss and not acute hemorrhage. The etiology is not known but there is a prominent association with connective tissue disorders. It can usually be treated by endoscopic argon coagulation but occasionally antrectomy is necessary.¹⁷⁸

Angiodysplasia of the Stomach and Small Intestine

Angiodysplastic lesions may occur throughout the GI tract. Similar to colonic lesions, they appear as minute, flat, or slightly raised red lesions with round or stellate shapes. The margins are characteristically sharp with a pale mucosal halo surrounding the lesion. The lesions are frequently multiple and are found most commonly in the stomach and duodenum, although esophageal and small intestinal involvement has also been described.

In general, these lesions may be diagnosed by endoscopy, although their minute size and sessile nature may complicate their detection. The lesions may also be readily mistaken for submucosal hemorrhage associated with acute gastritis or trauma artifact from an NGT or the endoscope. The lesions may also be demonstrated arteriographically since they have many of the features described for colonic vascular ectasia.

Endoscopic injections of sclerosants, electrocoagulation, and laser photocoagulation have all been used to treat gastroduodenal angiodysplasia with good results. The multiplicity of lesions often necessitates several courses of therapy to eliminate recurring hemorrhage. Surgical resection of the gastric or intestinal wall containing the lesion as well as oversewing of the bleeding lesion have been reported to successfully control hemorrhage.

Aortoenteric Fistula

Although communication between the aorta and the intestine may occur as a result of aneurysmal disease or infectious aortitis (*primary aortoenteric fistula*), most of those encountered currently are due to the erosion of an aortic vascular prosthesis through the wall of the distal duodenum (*secondary aortoenteric fistula*). The incidence of aortoenteric fistula following aortic reconstructive surgery is about 1% with most of these fistulas arising from the proximal graft anastomosis. Secondary aortoenteric fistulas are believed to develop after prolonged contact of a prosthetic graft with a fixed segment of intestine. Ultimately erosion of the graft through the bowel wall results in a low-grade infection around the graft; involvement of the infection with the suture line leads to dehiscence of the anastomosis and massive hemorrhage.

The interval between aortic reconstructive surgery and the onset of GI hemorrhage may range from a

few days to many years; the median interval is about 3 years.¹⁷⁹ Most patients have an initial episode of GI bleeding (i.e., herald bleed) that is followed in hours, days, or weeks by catastrophic hemorrhage. Patients may also complain of back or abdominal pain and less commonly have fever or signs of sepsis from infection of the graft.

The diagnosis of an aortoenteric fistula must be considered in any patient with an aortic prosthesis or an abdominal aortic aneurysm who presents with GI hemorrhage. Endoscopy should be urgently performed following resuscitation to disclose evidence of an aortoenteric fistula or another cause of bleeding (e.g., peptic ulcer disease with stigmata of recent hemorrhage). If endoscopy fails to demonstrate an aortoenteric fistula or another convincing source of bleeding and the patient is not massively bleeding, computed tomography may be helpful in detecting perigraft infection or other evidence of an aortoenteric fistula. In patients who are actively bleeding, exploratory laparotomy with exposure of the proximal graft should be undertaken. Identification of an aortoenteric fistula or erosion requires resection of the graft with extra-anatomical bypass and repair of the duodenal wall, or aortic reconstruction using a variety of techniques such as aortic reconstruction with popliteal vein or human allografts.¹⁸⁰ The operative management of aortoduodenal fistulas is considered in greater detail in [Chapter 96](#).

Meckel Diverticulum

Bleeding from a Meckel diverticulum is a common cause of lower GI hemorrhage in children but is rare in older adults. Meckel diverticula are present in approximately 2% of the population. The lifetime risk of a complication from a Meckel diverticulum is about 4%.¹⁸¹ About 25% of patients with symptomatic Meckel diverticula present with hemorrhage.¹⁸² In a series of 17 patients who bled from Meckel diverticula, 11 experienced frank hemorrhage while 6 had chronic occult blood loss. The incidence of GI hemorrhage is greatest in the first decade of life and steadily decreases from that point. In one series, no patient older than 40 years of age, and only one patient older than 31 years, bled from a Meckel diverticulum,¹⁸² although it has been reported in the very elderly.¹⁸³ The pathogenesis of this bleeding involves the occurrence of ectopic gastric mucosa with peptic ulceration of adjacent bowel wall. Although these lesions may be demonstrated by enteroclysis, abdominal scintigraphy following the intravenous injection of ⁹⁹technetium-pertechnetate demonstrates the ectopic gastric mucosa within the diverticulum, suggesting the correct diagnosis. Treatment consists of resecting the diverticulum with adjacent bowel. Diverticulectomy alone will be associated with persistence of the ulcer and the possibility of recurrent hemorrhage.

Small Intestinal Diverticulum

Diverticular disease of the small intestine is another uncommon cause of either UGI hemorrhage (duodenal) or LGI hemorrhage (jejunoileal diverticula).¹⁸⁴ The pathogenesis is similar to that of colonic diverticula with erosion of a vasa recta through the diverticular wall and the acute onset of massive hemorrhage. Depending on the location of the diverticulum, patients may present with either hematemesis, melena, or hematochezia. Hemorrhage from this source can be a vexing diagnostic problem because jejunoileal lesions are beyond the reach of the gastroscope and bleeding from duodenal diverticula may be difficult to discern. Mesenteric angiography or intraoperative enteroscopy may localize the site of hemorrhage in actively bleeding patients. Segmental resection of the involved intestine is the treatment of choice.

Hemorrhage Following Endoscopic Procedures

Significant hemorrhage can occur following endoscopic biopsy, sphincterotomy, and other traumatic procedures. Fortunately these complications are uncommon. Colonoscopy may rarely cause clinically significant bleeding (0.1% to 0.2%).¹⁸⁵ Biopsy of lesions increase the risk up to 10-fold. Usually this is minor and self-limited and may occur up to 12 days after the procedure.¹⁸⁶ The bleeding site can be confirmed by tagged red cell scanning, arteriography, or colonoscopy. Arteriography and colonoscopy can be used therapeutically as described previously. Endoscopically placed bands such as those used for esophageal varices, have also been reported to be successful in arresting hemorrhage.⁹⁸ Surgical treatment is rarely required.

Hemorrhage following endoscopic biliary sphincterotomy occurs in approximately 2% of patients.¹⁸⁷ Mild immediate bleeding is common and is usually self-limited. Late hemorrhage usually occurs within 48 hours of the procedure but can occur many days after sphincterotomy.¹⁸⁸ More severe hemorrhage can usually be controlled by epinephrine injection,¹⁸⁸ making the need for operative treatment

uncommon.

Chapter 66

Ulcerative Colitis

Dorin T. Colibaseanu and David W. Larson

Key Points

- 1 Ulcerative colitis is a form of inflammatory bowel disease (IBD) largely limited to the mucosa and submucosa of the colon and rectum. This process is continuous, beginning at the rectum, and extending proximally for a variable distance.
 - 2 The acute indications for surgical intervention are fulminant disease, toxic megacolon, and bleeding. Failures of medical management, dysplasia, or cancer are indications for elective surgery.
 - 3 The intestinal manifestations of ulcerative colitis (UC) are cured by removal of the colon and rectum.
 - 4 Current surgical options depend on the acuity of presentation of the disease; minimally invasive methods should be employed when clinically indicated and technically feasible.
 - 5 Proctocolectomy with ileal pouch-anal anastomosis (IPAA) provides patients with a continent reservoir; a Brooke ileostomy is available for those patients who do not qualify for a pouch construction.
 - 6 Although perioperative and late complications after ileal pouch-anal reconstruction are not uncommon, the vast majority of patients enjoy a high quality of life after surgery.
-

INTRODUCTION

1 Ulcerative colitis (UC) and Crohn disease (CD) affect more than 1.4 million people in the United States. Together these two diseases have many common characteristics, yet they are two distinct entities.¹ UC is a nonspecific and idiopathic inflammatory bowel disease (IBD) of unknown etiology that primarily affects the mucosa and submucosa of the colon and rectum. It is characterized by recurring episodes of inflammation. While medical treatment remains the mainstay of UC management, it does not represent a cure.

EPIDEMIOLOGY

Determining the exact incidence of UC is difficult because mild cases might never be reported, and the disease itself is uncommon. In North America, the reported incidence varies between 2.2 and 19.2 cases per 100,000 person-years.¹⁻⁵ Global incidence and prevalence of UC tends to be the highest along northern latitudes, and lower in Asia and the Middle East.⁵⁻⁸ Over time, the incidence of IBD has increased globally, especially the last 20 years.^{9,10}

Etiology and Risk Factors

Development of UC is likely due to the interaction of multiple genes, and environmental factors. It is more common in Jewish and Caucasian populations, and infrequent in black and Hispanic populations.^{11,12}

Genetics

Both environmental and genetic risk factors have been implicated in the development of UC; however, the exact pathogenesis has not been fully elucidated. Up to 20% of the patients with IBD are part of families with other afflicted members. It is recognized that there is a non-Mendelian genetic predisposition to developing UC. Monozygotic twin concordance rate for UC varies between 10% and 19%, and it increases over time.¹³⁻¹⁵ The offspring of parents with UC can have a risk of developing UC as high as 33%.¹⁶ Genetic concordance in CD is higher than in UC, and more than 100 loci have been

associated with increased risk for developing IBD (Table 66-1).¹⁷⁻²¹ Major histocompatibility complex HLA-DR2 is associated with UC, and there are at least 15 distinct loci that are associated with risk of developing UC.²²⁻²⁵

Environmental Factors

There remains a bimodal distribution of UC, which typically develops between 15 and 40 years of age and then in a smaller subgroup later in life between 50 and 80 years (Fig. 66-1).²⁶ UC appears to be slightly more common in men.^{27,28}

Table 66-1 Genes Commonly Implicated in Ulcerative Colitis and Crohn Disease

UC	Crohn's	UC and Crohn's
IL22	NOD2	JAK2
IL22	IRGM	IL12B/p40
IL10	ATG16L1	STAT3
ECM1	IBD5/5q31	IL23R
IFNg	5p13/PTGER4	Nkx2.3
ARPC2	ICOSLG	3p21/MST1
OTUD3	LRRK2	CCNY
PLA2G2E	ITLN1	CDKAL4
	CCR6	TNFRSF6B
	PTPN2	IL18RAP
	TNFSF15(TL1A)	PCMG1
	DLG5	
	NLRP3	
	OCTN1	
	ZNF365	
	10q21	

Figure 66-1. Age-specific incidence of UC in Midwestern US population. (Adapted from Loftus CG, Loftus EV Jr, Harmsen WS, et al. Update on the incidence and prevalence of Crohn’s disease and ulcerative colitis in Olmsted County, Minnesota, 1940–2000. *Inflamm Bowel Dis* 2007;13:254–261.)

Diet rich in saturated fats, and refined sugar has been associated with higher incidence of UC. Physical activity however, is not strongly associated to incidence of UC.²⁹⁻³¹ Smoking appears to have a protective effect for UC; conversely former smokers have an increased risk of UC compared to those who never smoked.³²⁻³⁴ The apparent protective effect of smoking extends to some of the extraintestinal manifestations of UC, in particular primary sclerosing cholangitis (PSC) and occurrence of pouchitis.^{35,36} Interestingly, an appendectomy also has a protective effect from developing UC, though the mechanism is essentially unknown. Large, retrospective studies have shown a protective effect of 55% to 70%,³⁷⁻⁴¹ especially if the findings at the operation were consistent with appendicitis or lymphadenitis.³⁹ The mechanistic theories proposed for this interesting finding include the notion that as the body’s immune system responds to the inflammatory process of appendicitis, it adapts such that the inappropriate inflammatory process that defines UC never occurs. The environmental risks for development of CD and UC have some similarities but the diseases are in essence distinct entities (Table 66-2).

CLINICAL FEATURES

UC symptoms parallel the degree of the disease. Typically, UC affects the rectum, extending proximally in a continuous fashion, and can involve the entire colon. Most commonly the distal colon is involved for various length, however, approximately 20% of the time, patients present with pancolitis.⁴² The classic symptoms of UC are diarrhea, and rectal bleeding. Additional symptoms include tenesmus, urgency, and colicky abdominal pain.⁴³ Persistent pain is uncommon, and often can represent severe disease with inflammation extending to the serosa.⁴⁴ The sensation of constipation and incomplete evacuation can occur if there is severe rectosigmoid inflammation and spasm. As the disease progresses, systemic symptoms of fever, anorexia, weight loss, and malaise ensue. Severity of disease can be calculated using the Mayo Severity Index Calculator ([Table 66-3](#)).⁴⁵ Other calculators exist.

Extraintestinal Disease

Hepatobiliary

Approximately 3% to 5% of UC patients develop PSC. Generally, the patients are asymptomatic, though as the disease progresses liver enzyme elevation, pruritus, fatigue, chills, and right upper quadrant pain can develop. The risk of acquiring PSC is independent of colonic UC activity, and the risk persists after proctocolectomy. In addition, PSC is an independent risk factor for developing dysplasia/cancer in patients with UC.⁴⁶

Ophthalmologic

Greater than 3% of patients with UC can develop iritis, episcleritis, or uveitis. Episcleritis severity can parallel GI symptoms, but uveitis does not match GI disease activity. Though uveitis is less common, the disease is more severe, and if not promptly treated can result in blindness. Topical steroids and infliximab have successfully been used in treating UC uveitis.⁴⁷

Table 66-2 Clinicopathologic Features of Ulcerative Colitis vs. Crohn’s

Common Clinicopathologic Characteristics of IBD		
Manifestation	UC	CD
Bleeding	Common	Rare
Crypt abscesses	Common	Rare
Rectal involvement	Common	Rare
Small bowel involvement	Rare	Common
Transmural inflammation	Rare	Common
Bowel wall fissures	Rare	Common
Fibrosis	Rare	Common
Fistulas	Rare	Common
Perianal disease	Rare	Common
Ulcers	Rare	Common
Cobblestoning	None	Common
Pattern of involvement	Continuous, distal to proximal, mucosal	Skip lesions, transmural

Table 66-3 The Mayo Severity Index

Stool Frequency (Total number of stools/day) (3-day average) 0 = Normal number of stools for this patient 1 = 1–2 stools/day more than normal for this patient 2 = 3–4 stools/day more than normal for this patient 3 = >5 stools/day more than normal for this patient
Rectal Bleeding (3-day average) 0 = No blood seen 1 = Streaks of blood with <50% of stools 2 = Obvious blood seen with >50% of stools 3 = Blood alone passed
Physician's Global Assessment (PGA) 0 = Normal 1 = Mild disease 2 = Moderate disease 3 = Severe disease
Finding of Flexible Proctosigmoidoscopy 0 = Normal or inactive disease 1 = Mild disease (erythema, decreased vascular pattern, mild friability) 2 = Moderate disease (marked erythema, absent vascular pattern, friability, erosions) 3 = Severe disease (spontaneous bleeding, ulceration)

Cutaneous

Manifestations of UC can include erythema nodosum and pyoderma gangrenosum (Fig. 66-2). Erythema nodosum generally follows the disease progress of the GI symptoms, occurring in up to 4% of patients with UC.⁴⁸ These violet subcutaneous nodules can be treated with topical steroids, though most commonly, systemic treatment of GI symptoms will also help with erythema nodosum. While pyoderma gangrenosum occurs less frequently than erythema nodosum, its treatment is more difficult as the disease course of pyoderma gangrenosum does not always parallel UC activity. Infliximab has shown some promise in treating pyoderma gangrenosum.⁴⁹

Musculoskeletal

These conditions are responsible for the most frequent extraintestinal complaints. Sacroileitis and ankylosing spondylitis are associated with UC flairs, and remissions. Carriers of HLA-B27 are especially prone to ankylosing spondylitis. Successful treatment of sacroiliitis with NSAIDs does not preclude progression of spondylitis. Methotrexate has also been successfully used, and there are increasing data of successful use of anti-TNF agents.⁵⁰

DIAGNOSIS

Physical examination is often unrevealing, though generalized pain is often an indicator of severe disease. A triad of tachycardia, fever, and leukocytosis are indicators for systemic toxicity and should alert the clinician of impending need of surgical intervention. Vague discomfort, and perianal irritation are common findings due to bowel movement frequency.

Imaging

Conventional x-rays can be useful in the rare cases of obstruction and/or perforation. The use of contrast studies allow for the identification of signs of severe inflammation with loss of haustral markings, although they have largely been replaced by more modern imaging modalities. Figure 66-3 shows distended colon with loss of haustral markings, concerning for toxic megacolon.

Abdominal computed tomography with oral and/or rectal contrast and CT enterography protocols are the modern imaging techniques of choice and provide additional information regarding the severity of disease. The presence of fistulas, phlegmon, mass, or abscess is an indication of a disease process other than UC as these findings may in fact represent other diagnoses such as Crohn, diverticulitis, and cancer.

MRI has the advantage of limiting ionizing radiation exposure, benefiting the young especially, and those that potentially may require multiple imaging studies over the years. Additionally, MRI has the

capability of improved soft tissue differentiation. Particularly in the last decade, developments in MRI hardware and software has made this imaging modality an especially valuable tool in diagnosing and following patients with UC (Fig. 66-4).⁵¹

Figure 66-3. Abdominal x-ray of Megacolon Beck DE, Roberts PL, Saclarides TJ, et al. ASCRS. New York, NY: Springer; 2011.

Ultrasound and nuclear medicine may provide complementary information in addition to CT and MRI but are currently used less commonly and are utilized only for specific situations.

Endoscopy

Endoscopic evaluation is the most useful tool in diagnosing UC. Often the first step is a flexible sigmoidoscopy or rigid proctoscopy especially in cases of acute flare, when a full colonoscopy may pose a significant risk of perforation. The macroscopic appearance of the colon through the endoscopy can often differentiate between UC and CD. Biopsies are taken, in addition to stool samples to rule out bacterial pathogens and ova/parasites.

Pathology

Macroscopic Appearance

UC always starts in the rectum and progresses proximally (Fig. 66-5). Although UC is a mucosal and submucosal disease, in the acute setting of severe disease, the colon wall can be inflamed transmurally, mimicking CD.

The mucosa is involved in a confluent manner, and unlike CD, fibrosis and strictures are uncommon (Table 66-2). Most importantly, the presence of stricturing disease in UC represents the potential for malignancy, which must be excluded. Superficial fissures are common, as are pseudopolyps. On occasion, the rectum can appear to be spared, especially if topical medication has been used through enema or suppository.

Figure 66-4. MRI demonstration of active UC with rectal wall thickening, increased vascularity, and inner layer hyperenhancement. Courtesy of Dr. William Reed.

Microscopic Appearance

UC is an inflammatory process, thus neutrophil infiltration is common, and crypt abscesses form, which then coalesce to form ulcers (Table 66-2). Goblet cell mucin depletion and crypt distortion are common in UC. In long-standing UC, special attention must be given to the presence of dysplastic lesions, though these can be difficult to identify in cases of acute inflammation.

Differential Diagnosis

Bloody diarrhea can be a symptom of an infectious process. It is important to rule out pathogenic bacteria, parasites, and viruses. *Clostridium difficile* should specifically be excluded. Other infectious agents include Salmonella, *Escherichia coli* (O157:H7 strain), Campylobacter, and Entamoeba.

In nearly 10% of the cases, it is impossible to definitively classify the colitis. Over time, a portion of these indeterminate colitis cases will separate as either Crohn's or UC. However some will remain as indeterminate, especially if the serology assessment is inconclusive (for both ASCA and p-ANCA).⁵²

MANAGEMENT

Medical Management

Corticosteroids

Corticosteroids are frequently used as the primary rescue medication in treatment of acute flares of UC. Corticosteroid efficacy in inducing remission approaches 70%.^{53,54} Lack of improvement or disease progression with corticosteroid treatment is followed by biologic agent treatment (as a secondary rescue medication) or surgery.⁵⁵ Overall, the use of corticosteroids is decreasing, largely due to the increase in the number and treatment effectiveness of the biologic agents available. Corticosteroids should not be used for maintenance of remission due to their side-effect profile. Topical corticosteroids such as budesonide or rectal preparations can be effective and have a reduced side-effect profile. However, these medications are not typically used in the acute setting. The side-effect profile of systemic corticosteroids includes osteoporosis, diabetes, glaucoma, and infections, among others. Long-term use of corticosteroids is associated with an increase in mortality.⁵⁶

Aminosalicylic Acid Compounds (5-ASA)

These compounds are most commonly used as first line medications in treating mild UC, and can be used in maintenance of remission. Concomitant use of oral and rectal preparation is effective in maintenance of UC remission.⁵⁷ Noncompliance with 5-ASA maintenance therapy is associated with a fivefold increase in disease recurrence.^{58,59} Cases of nephrotoxicity have been reported with use of 5-ASA, though these cases are rare. Folate must be supplemented with treatment of 5-ASA as its absorption is impaired by 5-ASA.

Immunomodulators (Nonbiologic)

Cyclosporine can be used as an effective first-line or second-line rescue medication (e.g., after failed corticosteroid treatment) and is currently used at a limited number of centers. It is most commonly used as first-line treatment, and serves as an option for those patients recalcitrant to corticosteroid treatment.⁶⁰ Close monitoring of cyclosporine levels is necessary. Cyclosporine toxicity profile includes

hypertension, renal failure, and infections.⁶¹

Figure 66-5. UC endoscopic findings with A: Loss of normal vascular pattern. B: Contact bleeding. C: Granularity. D: Ulceration and friability. E: Colonic stricture. (Reproduced with permission from Corman ML. *Colon and Rectal Surgery*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

Mercaptopurine (6-MP). 6-MP and its prodrug azathioprine are thiopurine analogs and have been used extensively in the treatment of UC. They are superior to 5-ASA treatment alone and are often clinically used in combination with either 5-ASA or anti-TNF drugs in treating IBD.⁶² Skin cancers and lymphoma have been reported with thiopurine.⁶³ Severe infections have been reported with use of these medications.⁶⁴ Liver enzyme elevations, pancreatitis, and cholestasis have also been seen, and the most commonly reported side effects are headaches, hypersensitivity, and abdominal pain.

Methotrexate. This medication is rarely used in UC, more commonly used in CD, although its side-effect profile makes its use difficult even in CD. Hepatotoxicity bone marrow suppression and central nervous system side effects limit the use of this medication.⁶⁵

Biologic Immunomodulator Agents

Infliximab is the first anti-TNF medication that was used in treatment of CD in 1988, then shortly after became FDA approved for use in UC. Infliximab is chimeric mouse–human monoclonal antibody. Infliximab has been found to successfully induce remission in over 60% of the UC patients treated in the ACT 1 and 2 trials.⁶⁶ Extended follow-up of the patients in the trial found that 15% of patients who initially responded to infliximab subsequently had to discontinue therapy due to side effects or loss of efficacy.⁶⁷ Approximately 9% of patients continued to be treated with infliximab for 3 years. Adalimumab, certolizumab, and golimumab were then added to the list of the anti-TNF agents, a list that is continually growing. Both infliximab and golimumab have been efficacious in inducing and maintaining remission in UC patients.^{66,68,69} Among the biologic agents' side-effect profile, infection

remains a persistent concern.^{70,71} The data regarding malignancy risk with anti-TNF agents are mixed; there appears to be an increased risk of lymphoma.⁷²

SURGERY

Indications of Surgical Intervention

2 Approximately 20% to 30% of patients that develop UC will ultimately need an operation.^{73,74} Indications for surgery include fulminant colitis, toxic megacolon, uncontrolled bleeding, neoplasia, recalcitrance to medical management, unrelenting extraintestinal manifestations, and development of significant side effects of the treatment medications.

Toxic Megacolon

This is a life-threatening, surgical emergency. Toxic megacolon (Fig. 66-3) is not specific to UC; it can occur in cases of infectious colidities (*C. difficile*, Shigella, Salmonella, etc.), or ischemic colitis. Patients present with systemic toxicity, heralded by high fever, tachycardia, severe abdominal pain, leukocytosis or leukopenia, and a distended, thickened colon. Immediate, aggressive resuscitation and broad-spectrum antibiotics should be started, and all opiates, and antidiarrheal agents should be ceased. An infectious cause should immediately be ruled out as treatment for UC includes corticosteroids, treatment which would be detrimental to the management of infectious colidities. Toxic megacolon is seen most often in new cases of UC, but acute exacerbations of chronic UC can also lead to toxic megacolon. Nonoperative treatment can be attempted, however, any signs of instability, worsening of the clinical condition, or lack of improvement within 3 to 5 days should be followed by prompt operative treatment. In one study, nearly half of all patients with UC treated nonoperatively subsequently required surgery, most under urgent or emergent circumstances.⁷⁵ In the contemporary era of biologic options, failure can occur in up to 30% in the short term (within 30 days), and it is unclear in the long term how many of these patients will need a colectomy, and under what clinical circumstances.⁷⁶

Fulminant Colitis

Patients presenting with tachycardia, fever, and surgical tenderness need aggressive resuscitation. Intravenous steroids should be started promptly, and the patients should be offered surgical treatment immediately if their condition deteriorates. In general terms, patients should improve within 3 to 5 days on medical therapy. Early surgical intervention has shown a clear decrease in the mortality rate in patients failing medical therapy.^{77,78}

Uncontrolled Bleeding

Less than 5% of the patients affected with UC have life-threatening bleeding. In this rare circumstance an abdominal colectomy is necessary. These cases represent approximately 10% of the emergent colectomies performed in UC.⁷⁹

Carcinoma/Dysplasia

Stage for stage, cancer in the setting of UC has the same prognosis, however, cancer is often detected at a later stage in UC. Nearly 20% of the patients with colorectal carcinoma in the setting of UC are unresectable at the time of diagnosis.^{80,81} The highest risk of colorectal cancer (CRC) is seen in those UC patients with a long history of pancolitis, a risk that accrues after 8 to 10 years of UC. The absolute risk of CRC development is less than 8% after 30 years of UC.⁸² Patients with over 8 years of UC, particularly with extensive colitis, should undergo colonoscopy yearly, or every 2 years.⁸³ It is often difficult to identify dysplasia in inflamed colon, and thus at the time of colonoscopy, random biopsies are obtained in addition to sampling any polyps, adenomas, or dysplasia-associated mass or lesions (DALM). Undetected synchronous cancer can coexist in areas of low- and high-grade dysplasia.⁸⁴ Thus, high-grade dysplasia, nonadenoma-like DALMs, and multifocal dysplasia are indications for proctocolectomy, though there is ongoing research in this area.

Recalcitrance to Medical Treatment

Some patients do not respond fully to medical treatment, and either have persistent symptoms despite maximal medical treatment, or respond only to corticosteroids, and are thus subject to the side effects of long-term corticosteroid treatment.

Extracolonic Manifestations

3 Proctocolectomy can help with some of the extracolonic manifestations, though PSC, pyoderma gangrenosum, and ankylosing spondylitis specifically do not respond to surgery. Proctocolectomy has shown to help with erythema nodosum, and small/large joints arthralgia, though the role of colectomy is not completely defined in the treatment of extraintestinal manifestations of UC.⁸⁵

Figure 66-6. Brooke ileostomy.

Surgical Management

Unlike CD, proctocolectomy is curative for gastrointestinal UC. As the disease begins in the rectum and involves the colon proximally for a variable distance, ultimately proctectomy should be performed for definitive treatment of UC.

Multiple surgical options are available, with treatment dependent on the urgency of presentation, and general condition of the patient. Currently, in emergency conditions, the operation of choice is a subtotal colectomy with preservation of the rectum, and a Brooke ileostomy (Fig. 66-6). Resection of the rectum in the emergent setting should be avoided if possible, to both to allow continent reconstruction at a later time and to avoid a perineal dissection in suboptimal conditions. Mobilizing the rectum unnecessarily in emergent conditions disrupts the presacral planes, and will make later reconstruction more difficult. In addition, the ureters and pelvic nerves are put at risk. Additional consideration should be given to the level of ileal transection proximally, keeping in mind that a later ileal pouch reconstruction is dependent on the ileocolic arterial arcade, and thus all efforts should be made to keep this vascular network intact.

Abdominal Colectomy with a Brooke Ileostomy

The location of stoma should be marked preoperatively with the help of an enterostomal therapist if at all possible. Managing a poorly placed stoma is a major source of frustration for the patient postoperatively. Additionally, appropriately training and educating the patient preoperatively with regard to the care of their stoma is critical to their postoperative progress.

4 A minimally invasive approach should be attempted if the patient is stable and the surgeon is sufficiently comfortable with the operation.^{86,87} A systematic technique should be employed, and with sufficient training and experience excellent outcomes can be achieved.⁸⁸

The operation is started in the lithotomy position. If there is a concern regarding visualization of the ureters, it is recommended that ureteral stents be placed. Though they do not reduce the rate of ureter injury, they do help identify an injury immediately, and facilitate prompt repair.⁸⁹ The colon is mobilized in a lateral to medial fashion most commonly (Figs. 66-7 and 66-8), and unless there is concern of dysplasia/neoplasia, the vessels (ileocolic, middle colic, and inferior mesenteric artery branches) can be transected distally, facilitating safer mobilization. Particular attention should be paid to the splenic flexure, as a splenic tear will unnecessarily complicate the operation.

Once the colon has been completely mobilized and the vessels have been divided, the distal ileum can be transected. Particular attention must be paid to the integrity of the ileocolic vessel arcade, as the subsequent ileal pouch construction is largely dependent on these vessels. The colon can then be extracted through the ileostomy site, or through either a low vertical midline or a Pfannenstiel incision. The terminal ileum can then be extracorporialized and a Brooke ileostomy can be constructed (Fig. 66-6). It is critical to make sure that the small bowel mesentery is not twisted before “brooking” the ileostomy.

Figure 66-7. Colon mobilization. **A:** right colon. **B:** transverse colon. **C:** left colon.

Figure 66-8. Mobilized colon with vessels divided, and stapled at the rectum. This specimen is ready for extraction; the ileum can be transected intracorporeally, or after specimen is extracorporealized.

Proctocolectomy with Brooke Ileostomy

Abdominal colectomy is performed as above. In cases of rectal dysplasia or cancer, a total mesorectal excision is necessary. Patient is placed in Trendelenburg position and all bowel is displaced in the upper abdomen. The sigmoid and rectum are placed on tension, and any adhesions are freed. If the uterus and ovaries prevent visualization or adequate dissection, they are affixed in place by passing a 0-Prolene stitch through the abdominal wall, through the uterus, and back through the abdominal wall. Retracting the uterus anteriorly will help with visualization and dissection in the plane posterior to the vagina. The rectal mobilization is commenced by placing the rectum on cephalad and anterior traction. The peritoneum on the right of the rectum, medial to the ureters and the pelvic nerves is incised. This embryologic plane is followed cephalad just posterior to superior rectal artery along its course, tracing it proximally to the inferior mesenteric artery (IMA). Careful dissection just posterior to the IMA pedicle toward the left pelvic sidewall will reveal the left ureter; its location is almost always higher than expected. Lateral (on the left) to the ureter, the gonadal vessels are found. The ureter is retroperitoneal, and as such all efforts should be made to avoid incising the retroperitoneum, and

instead, it is safer if this embryologic layer is left undisturbed. Following this shiny layer superiorly, one can easily carry the dissection cephalad until the IMA is identified and skeletonized. In the absence of neoplasia, it is unnecessary to perform a high (proximal) ligation of the IMA, though by doing so, one simplifies the dissection. Once the IMA (or the left colic artery) is identified and skeletonized, it can be divided with the appropriate instrument, after making sure that both ureters are well out of the field.

Carrying the pelvic dissection distally, the pelvic nerves and the ureters should be clearly identified and protected. Meticulous dissection can be done relatively bloodlessly. During anterior dissection of the rectum, all effort should be made to continue the dissection posterior (on the rectum side) of the Denovilliers fascia, specifically in men, to avoid sexual dysfunction. Similarly, during posterior mobilization of the rectum particular attention should be given to identifying the presacral fascia, as dissection posterior to this layer puts at risk the presacral vessels which can result in troublesome and sometimes life-threatening bleeding. Once the dissection is carried out to the pelvic floor circumferentially, a clamp can be placed on the proposed transection site, and the distance from the anal verge can be assessed by a simple digital rectal examination. If the distance is appropriate then the perineal dissection can follow. The patient is placed in Trendelenburg position, with both feet raised to afford exposure to the perineum. The dissection plane starts in the intersphincteric plane. This dissection leaves the external sphincter in situ, and can be incorporated in closing the perineal incision, which decreases the complication rate. This intersphincteric plane is followed proximally and circumferentially with particular attention anteriorly, to avoid injury to the vagina in women and urethra in men. Once the intra-abdominal plane is reached, this part of the dissection is done.

Figure 66-9. Distal rectal transection, (A) stapled above the dentate line, or (B) a mucosectomy in preparation for a hand-sewn anastomosis.

Proctocolectomy with Ileal Pouch-Anal Anastomosis (IPAA)

5 The colectomy and rectal mobilization are performed as above, however, once one reaches the pelvic floor the rectum is transected approximately 1 cm above the anorectal ring with the stapler (Fig. 66-9A). This rectal cuff will allow for better function, but will require surveillance as it is at risk for cuffitis, and neoplasia. Alternatively, a mucosectomy can be done (Fig. 66-9B) with a subsequent hand-sewn IPAA anastomosis, though this is mostly done in cases of distal neoplasia, and poorer function is observed.

Once the proctectomy is finished, a pouch is fashioned from the terminal ileum. Multiple configurations are possible; the J-pouch configuration is the most popular in the United States (Fig. 66-10). This is constructed by first aligning the terminal ileum into a J-configuration. It is necessary for the apex of the pouch (the end connection of the pouch to the anus) to reach the rectal cuff or anus. Usually, if the apex can be stretched without tension beyond the symphysis pubis, the pouch should reach the anastomosis site without undue tension. Multiple maneuvers can be done to “lengthen” the reach of the pouch, and are beyond the scope of this discussion. The pouch is usually between 10 and 20 cm in length, and ultimately optimizing reach has some effect on how long the pouch is. Once the apex location is decided on, the two limbs of the ileum are aligned with interrupted suture. An enterotomy is made at the apex of the pouch, and a stapler is used to fashion a common channel between the two limbs of ileum. The pouch can then be attached by using an EEA stapler device (placing the anvil in the J-pouch, and firing pin through the rectal pouch), or by performing a hand-sewn anastomosis (Fig. 66-11).

Figure 66-10. IPAA construction and anastomosis. (A) terminal ileum alignment for (B) common channel creation. C: EEA anvil attachment at the apex of the pouch.

Figure 66-11. Anastomosis of the J-Pouch with (A) stapled anastomosis and (B) hand-sewn anastomosis.

IPAA-Postoperative Complications

6 The majority of patients who have an IPAA report high quality of life. Small bowel obstruction occur in up to 20% of patients, most commonly managed nonoperatively.⁹⁰ The J-pouch is at risk for postoperative abscess, fistula, and pelvic sepsis, which can occur anytime after the pouch formation. Immediate intervention with drainage and antibiotic treatment to control the infection is key, as prolonged infection puts the pouch at risk.^{91,92}

Pouchitis is a nonspecific inflammation of the pouch that occurs in up to 40% of the patients.⁹³ This is the most common complication after IPAA. Pouchitis is treated initially with oral antibiotics. If pouchitis does not resolve, pouch evaluation using endoscopy is undertaken, with pouch mucosa biopsy, and further evaluations can include testing for infections, such as *C. difficile*. Other medications that have shown to help treat pouchitis are corticosteroids, budesonide, 5-aminosalicylic acid, and allopurinol.⁹⁴

Corticosteroid use does not preclude IPAA construction, though a slightly higher rate of anastomotic

leaks is observed, thus, usage of a diverting ileostomy should be considered in this patient population.⁹⁵ The effect of preoperative use of anti-TNF agents is not clear and limited to nonrandomized studies.

Routine surveillance of the pouch for dysplasia is not essential, however, surveillance of the rectal cuff or transitional zone is necessary (both stapled and hand-sewn anastomoses). The incidence of carcinoma in the rectal remnant/anal transition zone is rare but reported.⁹⁶

Proctocolectomy with Koch Pouch

This is the second continent option (in addition to IPAA). Only a few centers worldwide perform this procedure, and the technique is beyond the scope of this chapter.

In summary, UC is an inflammatory bowel condition influenced by both genetic and environmental factors. Its treatment includes increasingly sophisticated medical and surgical treatment regimens. An individualized, multidisciplinary treatment approach should be employed for each patient, at an institution that has the experience and volume to provide the most current and appropriate treatment.

Chapter 67

Colonic Polyps and Polyposis Syndromes

Robert S. Bresalier and C. Richard Boland

Key Points

- 1 Colorectal neoplasia develops through multistep carcinogenesis that involves the gradual accumulation of genetic and epigenetic alterations in the genome. This process usually requires the presence of some forms of genomic or epigenetic instability, and neoplasms may require several decades to evolve from their earliest stages to fully advanced disease.
 - 2 Genetic and familial factors play an important role in the genesis of both the sporadic (common) and syndromic forms of colorectal neoplasia, such as familial adenomatous polyposis and Lynch syndrome.
 - 3 Colorectal carcinoma usually evolves gradually from colorectal adenomas in clinically identifiable stages; removal of adenomas reduces the incidence of colorectal carcinoma.
 - 4 The genetic bases of familial adenomatous polyposis and Lynch syndrome (previously called hereditary nonpolyposis colorectal cancer) have been identified, which facilitate the early identification and diagnosis of affected individuals.
 - 5 A wide range of clinical heterogeneity is present in the familial colorectal cancer syndromes, and attenuated forms of familial adenomatous polyposis and Lynch syndrome can be subtle and a challenge to the clinician.
-

COLORECTAL POLYPS

The gastrointestinal tract accounts for more neoplastic disease than any other organ system in the body. In North America, neoplasms of the colon and rectum have attracted the greatest interest because of their relatively high incidence, and because appropriate intervention can dramatically modify the morbidity and mortality associated with them. The adenoma is the most common precursor of colorectal cancer, and early removal of adenomatous polyps can interrupt the natural history of the disease and prevent death.

Colorectal cancers can develop through one of at least three molecular pathways, and each variety appears to have some unique clinical and pathologic features.¹⁻³ The adenoma–carcinoma sequence is virtually canonical at this time and describes the common pathway taken by neoplasms that have “chromosomal instability.” It has subsequently been proposed that “serrated” polyps, especially those in the right colon, may be precursors of colon cancers with the microsatellite instability (MSI) phenotype. It is becoming increasingly important to understand the clinical behavior of colorectal neoplasms in the context of the genetic and molecular bases of these lesions.

Classification of Colorectal Polyps

The term polyp (from the Greek *polypous*, “morbid excrescence”) refers to a macroscopic protrusion of the colonic mucosa into the bowel lumen. This can result from abnormal growth of the mucosa or from a submucosal process that causes the mucosa to protrude into the lumen. Mucosal polyps can be sessile, protruding directly from the colonic wall, or pedunculated, extending from the mucosa through a fibrovascular stalk.

Mucosal polyps in the colon can be categorized as neoplastic, with malignant potential, and nonneoplastic, with no malignant potential (Table 67-1). Neoplastic polyps include benign adenomatous polyps that may evolve to carcinoma, adenomatous polyps that contain foci of intramucosal carcinoma (carcinoma in situ), and adenomatous polyps in which carcinoma has penetrated the muscularis mucosae (invasive carcinoma). A serrated polyp (sessile serrated adenoma [SSA] and traditional serrated adenoma [TSA]) appears to originate in a manner unique from typical adenomas, but is also a premalignant lesion. Instead of evolving through the traditional multistep pathway, SSAs in the

proximal colon appear to evolve through a pathway that involves both *BRAF* mutation and progressive methylation of DNA that result in the silencing of multiple genes. The fine details of this pathway remain to be elucidated. Sometimes a polyp is found in which carcinoma has completely obliterated the adenomatous tissue from which it arose (polypoid carcinoma).

Nonneoplastic mucosal polyps include hyperplastic polyps (HPs) (a form of serrated polyp which does not directly progress to cancer), juvenile polyps, Peutz–Jeghers hamartomas, and a variety of inflammatory polyps, including those associated with inflammatory bowel disease. Any submucosal lesion can expand to push the mucosa into the bowel lumen and thus appear as a polypoid lesion. Examples include lipomas, leiomyomas, colitis cystica profunda, pneumatosis cystoides intestinalis, lymphoid aggregates, primary or secondary lymphomas, carcinoid tumors, and other metastatic neoplasms.

Neoplastic Mucosal Polyps

Most colorectal cancers arise in pre-existing adenomatous polyps. Neoplastic mucosal epithelium evolves through a series of progressive, cumulative molecular and cellular steps that lead to altered proliferation, cellular accumulation, and glandular disarray. In some instances, the polyp also achieves the ability to invade and metastasize through the adenoma-to-carcinoma sequence.

Several lines of evidence support the assumption that colorectal adenocarcinomas arise from adenomatous polyps. The descriptive epidemiology of colonic adenomas parallels that of carcinomas, but the benign lesions occur earlier. Adenomas are rare in geographic regions with a low prevalence of colon cancer, and the distribution of adenomas in the colon parallels that of carcinomas. Adenomas often occur in anatomic proximity to colon cancers, and cancer risk is proportional to the number of adenomas present synchronously or metachronously in a patient. Cancer is often present in polyps removed endoscopically or surgically, and the risk for cancer is proportional to the degree of dysplasia or atypia in the polyp. Conversely, histologically evident residual adenomatous tissue may be found surrounding carcinomas. Most important, results from several studies indicate that the systematic removal of adenomatous polyps during screening sigmoidoscopy or surveillance colonoscopy decreases the risk for the development of colorectal cancers and death from this disease.

CLASSIFICATION

Table 67-1 Classification of Colorectal Polyps

Mucosal Polyps
Neoplastic
Benign
Adenomatous polyps
Tubular adenoma
Tubulovillous adenoma
Villous adenoma
Sessile serrated adenoma or polyp
Traditional serrated adenoma
Malignant
Carcinoma in situ
Invasive carcinoma
Polypoid carcinoma
Nonneoplastic
Hyperplastic polyps
Juvenile polyps
Peutz–Jeghers polyps
Inflammatory polyps
Normal epithelium
Submucosal Polyps
Lipomas
Leiomyomas
Colitis cystica profunda
Pneumatosis cystoides intestinalis
Lymphoid aggregates
Lymphoma (primary or secondary)
Carcinoids
Metastatic neoplasms

Pathogenesis

Molecular Biology

1 Genetic changes that lead to the development of adenomas (and carcinomas) can be loosely organized into three broad categories: alterations in proto-oncogenes, loss of tumor-suppressor gene activity, and abnormalities of genes involved in DNA repair (Fig. 67-1).¹⁻³ Several different mechanisms are involved in altering these genes. Typically, oncogenes become overactive by mutation, rearrangement, or amplification. Tumor-suppressor genes become inactivated by mutation or deletion, or silenced through promoter methylation. Tumor-suppressor genes require inactivation of both copies of alleles, making this process more complex. It is now clear, however, that the development of adenoma and carcinoma is always associated with the progressive accumulation of genetic changes, and this process is termed multistep carcinogenesis.¹⁻⁴

In familial adenomatous polyposis (FAP), Lynch syndrome (previously called hereditary nonpolyposis colorectal cancer [HNPCC]), and other familial syndromes, the first genetic alteration is inherited in the germline, and therefore present in every cell. Environmental factors or “accidents” occurring in the DNA from faulty replication or DNA damage are then required for the additional genetic mutations, termed somatic mutations, as the process moves toward cancer. The clinical phenotype for the inherited predispositions to gastrointestinal cancer is initially normal. The germline mutation provides the first alteration or “hit,” which greatly increases the likelihood of neoplasia and that the disease will occur at a younger age. FAP and Lynch syndrome account for about 3% to 4% of all colorectal cancers, but it is estimated that as many as 30% of colorectal cancers occur in the context of a positive family history, which is probably mediated by numerous subtle differences in DNA sequence (called single nucleotide polymorphisms, or SNPs) that exert small changes in risk.

“Sporadic” polyps and cancers are associated with multiple somatic mutations, all of which are caused by spontaneous decay of DNA, exogenous insults, or are accidents that occur during the replication of DNA. The occurrence of most cases of colorectal cancer has been attributed to the high frequency of cancer in the colon and rectum compared to other organs is a consequence of the number of stem cell divisions that occurs in human colon. To some degree, the occurrence of colorectal cancer is often a matter of “bad luck.”⁵

Destabilization of the genome is a prerequisite to carcinogenesis. This most commonly involves chromosomal instability, which is manifested as widespread chromosomal deletions, duplications, and rearrangements that produce aneuploidy. Alternatively, increased rates of mutations, often in tandemly repeated DNA sequences known as microsatellites (i.e., microsatellite instability or MSI) or a form of epigenetic instability called the CpG island methylator phenotype (CIMP), in which genes are inappropriately silenced by promoter methylation¹⁻³ are mechanisms that can lead to progressive multistep carcinogenesis. Genomic (or epigenetic) instability generates a large number of random alterations, which are often silent or lead to the extinction of the cell. However, occasional genetic alterations enhance growth and survival, and the successive accumulation of those changes will eventually facilitate the evolution of a neoplastic cell.

Cellular proto-oncogenes are a group of evolutionarily conserved genes that play a role in signal transduction and the normal regulation of cell growth. They function by being turned on when growth is stimulated and then turned off when sufficient growth has been achieved. Inappropriate activation of these genes, usually through mutation that activates the protein or rearrangement of the promoter sequences, leads to unregulated growth-regulatory signaling and excessive cellular proliferation. The prototypical oncogene in CRC is in *KRAS*, and mutations in this gene are progressively more frequent in larger, more advanced adenomatous polyps. The tumor-suppressor gene *APC* on chromosome 5q is critical to the evolution of the colorectal adenoma. Allelic losses of chromosome 5q occur early during carcinogenesis in the colon, and this is frequently the initial step in the evolution of colorectal neoplasia. *APC* acts as the “gatekeeper” of colonic epithelial proliferation, and inactivation of this gene will lead to net cellular proliferation and initiation of neoplasia in the colon. The protein produced by the *APC* gene plays a central role in regulating the intracellular concentrations of the transcription factor, β -catenin. β -catenin is highly expressed in cells at the base of the colonic crypt, where it stimulates proliferation. As the cell commits to terminal differentiation, the *APC* gene is expressed, which downregulates β -catenin by phosphorylation of the protein, targeting it for degradation.

Inactivating alterations in the *p53* tumor-suppressor gene are a critical step in the transition from adenoma to carcinoma, as the *p53* protein normally prevents cells with damaged DNA from progressing from the G1 to the S phase in the cell cycle. Alterations in *APC*, *p53*, and *KRAS* are the most common alterations in most CRCs. However, a subset of about 15% of CRCs are “hypermuted” and have a

different signature pattern of somatic mutations.⁶

Figure 67-1. Proposed sequence of molecular genetic events in the evolution of colon cancer. Carcinomas arise from an accumulation of events whose sequence has been defined for two of the carcinogenesis pathways. As illustrated here, tumors progress through the adenoma-to-carcinoma sequence along pathways marked by chromosomal instability (CIN) or microsatellite instability (MSI). At least one more pathway, characterized by promoter methylation of tumor-suppressor genes, serrated polyps, and cancers with variable degrees of microsatellite instability, is incompletely understood, and not shown here. ACF, aberrant crypt focus; TGF, transforming growth factor. (After Grady WM. Genomic instability and colon cancer. *Cancer Metastasis Rev* 2004;23:11; Grady WM, Carethers JM. Genomic and epigenetic instability in colorectal cancer progression. *Gastroenterology* 2008;135:1079–1099.)

The major form of hypermutation occurs when the DNA mismatch repair (MMR) system is inactivated. Germline mutations in the DNA MMR genes *MSH2*, *MLH1*, *MSH6*, and *PMS2* cause Lynch syndrome, which historically was called HNPCC.⁷ In the hereditary CRC syndromes, germline mutations inactivate one copy of the gene, and the other allele is inactivated by a “somatic” genetic event that occurs locally in an individual colonic epithelial cell. Loss of DNA MMR results in a diffuse mutational signature in the tumor called microsatellite instability, or MSI. This defect leads to the mutational inactivation of several key genes important for maintaining normal cellular behavior. The *transforming growth factor- β receptor II* (*TGF- β RII*) gene, for example, is mutated in 85% of MSI colorectal cancers. This inactivates the receptor, renders the cell unresponsive to TGF- β , and permits it to escape normal growth regulation. The MSI multistep carcinogenesis pathway to tumor development is seen in about 15% of all colorectal cancers,⁸ and progression from adenoma to carcinoma occurs in a shorter time period than occurs in the chromosomal instability pathway seen in most colorectal cancers, which is thought to require 10 to 20 years. MSI colorectal neoplasms appear to account for two clinical observations. First, the MSI pathway may account for the occurrence of cancers 1 or 2 years after a negative colonoscopy (“interval cancers”). Second, it may account for the relatively small number of adenomatous polyps found with MSI, since they may evolve into cancer in a shorter timeframe than usually occurs.

Histopathology and Malignant Potential

Adenomatous polyps are characterized according to their physical features, size, glandular structure, and degree of dysplasia, which all have important implications for clinical management. Polyps may be sessile, with a broad-based attachment to the colonic wall, or pedunculated, attached to the colonic wall by way of a fibrovascular stalk (Fig. 67-2). Whether a polyp is sessile or pedunculated previously determines whether the endoscopist can remove the polyp completely by snare polypectomy. Newer endoscopic techniques such as endomucosal resection (EMR) and endomucosal dissection (ESD) have

now allowed for resection of most sessile polyps. Diminutive polyps that measure 5 mm or less in diameter are not likely to contain high-grade dysplasia or invasive carcinoma. Malignant potential increases with polyp size in all histologic groups of adenoma.

Adenomas are classified histologically according to their glandular structure. Aberrant (dysplastic) crypts and microadenomas may be the earliest lesions detected in the flat mucosa of patients at risk. These enlarge and progress to macroscopic adenomatous polyps. Tubular adenomas are characterized by a complex network of branching adenomatous glands, whereas villous adenomas contain fronds or folds of mucosa that have overgrown their underlying stroma and project toward the colonic lumen (Fig. 67-3). Often, both histologic types coexist in a mixed tubulovillous adenoma.

All conventional adenomas, by definition, consist of dysplastic mucosa. The term dysplasia refers to abnormalities in crypt architecture (such as irregular branching or crowded “back-to-back” glands) and cytologic detail (enlarged, pleomorphic, and hyperchromatic nuclei with multiple mitoses and pseudostratification; Fig. 67-4). Dysplasia may be mild, moderate, or severe, depending on the degree to which these characteristics are present. Severe, or high-grade, dysplasia represents carcinoma in situ when the basement membrane has not been invaded. Extension into the lamina propria denotes intramucosal carcinoma. Invasion into the muscularis mucosae defines invasive carcinoma and the malignant polyp. The degree of dysplasia usually correlates with polyp size and the extent of villous architecture. Occasionally, nonmalignant adenomatous mucosa can be displaced below the muscularis mucosae, probably due to trauma associated with colonic motility. This must be distinguished from malignant invasion and is termed pseudoinvasion.

Figure 67-2. Mucosal polyps of the colon may be sessile, protruding directly from the colonic wall, or pedunculated, extending from the mucosa through a fibrovascular stalk. **A:** Large sessile polyp seen at colonoscopy. The polyp has a broad-based attachment to the mucosa. **B:** Pedunculated polyp seen at colonoscopy. The polyp is attached to the mucosa through a distinct stalk. **C:** Low-power photomicrograph of a pedunculated polyp (a tubular adenoma) cut in cross section to demonstrate its fibrovascular stalk

It is now recognized that some serrated polyps (characterized by a “saw-tooth” pattern of colonic crypts) may be precursors to carcinoma.⁹ HPs are typically small (diminutive polyps <5 mm) and are usually located in the distal colon and rectum. These are the most common type of serrated polyps (30% to 40% of all polyps and 80% to 90% of serrated polyps), and do not appear to have direct malignant potential. SSAs are distinct from conventional adenomas with respect to histology and molecular biology, and are typically nondysplastic. SSAs are characterized by distorted crypt bases and crypt dilation (Fig. 67-5) and by migration of the proliferative zone to the side of the crypt. SSAs are associated with *BRAF* mutations and CIMP, which can lead to epigenetic silencing of MMR genes such as *MLH1*, resulting in MSI. SSAs are typically right-sided, often flat (Fig. 67-5A), and may be covered by a so-called “mucous cap” (Fig. 67-5B). TSAs are the least common form of serrated lesion. They have villiform features and are typically protuberant or pedunculated left-sided lesions which contain areas of dysplasia. TSAs commonly have *KRAS* mutations and may give rise to microsatellite stable cancers. Serrated polyposis syndrome is a syndrome characterized by multiple serrated polyps (Fig. 67-5D).⁹⁻¹¹ These polyps are most often SSAs, but HPs and TSAs may also occur in this setting. The exact genetic defect and actual risk of malignancy associated with this syndrome are unknown.

Even though nearly all adenocarcinomas of the colon and rectum arise in adenomatous polyps, not all polyps evolve into carcinoma; in fact, most do not. The malignant potential of adenomatous polyps is related to polyp size and the histologic characteristics. Large polyps and those with predominantly villous architecture are more likely to contain coincident carcinoma (Fig. 67-6). These features are interdependent, however, because large polyps are more likely to be villous and dysplastic. Adenomas that measure 0.5 cm or less are most often tubular adenomas and rarely contain severe dysplasia or carcinoma (<0.5% in autopsy series). Likewise, only 1% to 2% of adenomatous polyps smaller than 1 cm contain carcinoma, but autopsy studies suggest that as many as 40% of adenomas greater than 2 cm contain cancer. Data derived from the examination of colonoscopic polypectomy specimens indicate similar trends but suggest a lower incidence of cancer-containing polyps.

Figure 67-3. Histology of adenomatous polyps. **A:** Tubular adenomas are characterized by a complex network of branching adenomatous glands (see also C). **B:** Villous adenomas consist of glands that extend straight down from the surface to the base as fingerlike projections; this pattern may be suggested by the gross appearance of these polyps. **C:** Tubulovillous adenoma.

Figure 67-4. Moderate dysplasia. Dysplastic mucosa is characterized by crowded, irregular glands and cells with enlarged, hyperchromatic nuclei of varied size and shape that do not line up uniformly on the basement membrane (pseudopalisading). Adenomas are composed of dysplastic mucosa in which the degree of atypia may vary. These changes precede the development of invasive carcinoma.

Epidemiology

Prevalence

The descriptive epidemiology of adenomatous polyps of the colon and rectum parallels that of colorectal carcinoma with relation to geographic distribution, age, prevalence, and genetic susceptibility. Like colorectal cancer, adenomas are common in Western countries such as the United States, but their prevalence traditionally has been low in parts of Asia (notably India), South America, and sub-Saharan Africa. Epidemiologic patterns for both adenomas and carcinomas are shifting with the acquisition of a “Western” lifestyle in many areas, particularly in Korea, Japan, and parts of Southeast Asia. Estimates of adenoma prevalence in the United States vary depending on the mode of data collection. Data from older studies were collected from autopsies and sometimes grouped all polyps together, whereas more recent studies have examined adenoma prevalence in the context of endoscopic screening. Studies using colonoscopy previously suggested an adenoma prevalence in patients without symptoms who are older than 50 years that ranges between 20% and 40%. More recent data from colonoscopies, where quality measures such as optimized cleansing preparations and withdrawal times have been employed, suggest adenoma detection rates (ADRs) which may exceed 50%.¹² Based on autopsy studies, one-half to two-thirds of people older than 65 years have colonic adenomas. Adenoma prevalence increases with age in all populations. Age-associated prevalence rates suggest that adenomas precede carcinomas in a given population by at least 5 to 10 years; it may be much longer, as polyps do not produce symptoms and, unlike cancers, dating the onset can only be estimated. Advancing age also correlates with multiplicity of polyps, polyp size, and higher degrees of dysplasia. In addition, 30% to 50% of patients with one adenoma have a synchronous adenoma elsewhere in the colon.¹³

Figure 67-5. Sessile serrated adenomas are often flat lesions located in the right colon (A). They may be obscured by “mucous caps” (B). Histologically they are characterized by a serrated surface epithelium, distorted crypt bases (C) and crypt dilation. Serrated polyposis syndrome presents with multiple serrated polyps (D).

Heredity

2 Heredity plays a role not only in FAP and Lynch syndrome but also in the development of sporadic adenomas. Sporadic (nonsyndromic) adenomatous polyps and colon cancers represent more than 95% of colorectal neoplasms. Clinical studies, including case-control and prospective analyses, indicate a two- to threefold increased risk for colon cancer among first-degree relatives of patients with a history of colonic adenoma or carcinoma. The relative risk increases when there are more affected relatives and when adenomas and carcinomas occur in young relatives. The impact of family history becomes prognostically insignificant in patients whose polyps are discovered after age 60. In most families, it is not possible to separate the impact of commonly shared genes from the impact of shared environmental exposures.

Anatomic Distribution

Autopsy series and colonoscopic examination of patients who do not have symptoms previously suggested that although adenomas are uniformly distributed throughout the colon, the distribution of clinically important larger adenomas is more similar to that of carcinomas, with a left-sided predominance. There appears to have been a “migration” over the past few decades, toward right-sided lesions in Western countries; 75% to 90% of SSAs are right sided, as are about 90% of sporadic CRCs with MSI.

Natural History

3 Adenomas are common in people older than 50 years, and although most carcinomas arise in

adenomatous polyps, relatively few adenomas progress to carcinoma. Little precise information is available on what proportion of adenomas evolves to carcinomas. In Norway, an example of a high-risk Western population, it has been estimated that colorectal adenomas are present in 29% of the population older than 35 years. The conversion rate from adenoma to carcinoma in this group (based on cancer incidence from multiple tumor registries) has been calculated to be 0.25% per year. In other words, the risk that a colorectal cancer will develop in a polyp-bearing person within 10 years is 2.5%. The annual conversion rates to invasive cancer for people with adenomas larger than 1 cm, villous components, and severe dysplasia have been estimated to be 3%, 17%, and 37%, respectively, based on these inferences. Data from a national colonoscopy database in Germany suggested that the annual transition rates from advanced adenoma (adenomas ≥ 1 cm, tubulovillous or villous adenomas, adenomas with high-grade dysplasia) to cancer is comparable among women and men, but strongly increases with age.¹⁴ Projected annual transition rates from advanced adenoma to cancer increased from 2.6% in age group 55 to 59 years to 5.1% in age group 80 and older among men, for example. These estimated rates in older age groups are in line with previous estimates derived from small case series but are considerably lower for younger age groups.

Figure 67-6. The relation of adenoma size and histology to malignant potential based on an analysis of 7,000 endoscopically removed polyps. The incidence of polyp-associated carcinoma determined from examination of polypectomy specimens is lower than that derived from early autopsy studies. (Data derived from Shinya H, Wolff WI. Morphology, anatomic distribution, and cancer potential of colonic polyps. *Ann Surg* 1979;1990:675.)

Both longitudinal follow-up of a small number of people with unresected adenomas and studies of age distribution provide indirect evidence that the evolution from adenoma to carcinoma takes at least 5 to 10 years. Age prevalence data from the National Polyp Study (NPS), for example, suggest that it may take as long as 5 to 10 years for normal-appearing mucosa to develop into a macroscopically visible adenomatous polyp, and an additional 3 to 5 years for invasive carcinoma to develop, in most instances. Case-control studies also support that the development of adenomas in the colon and the evolution to carcinoma occur slowly. Several studies, including the NPS, have estimated that the significant protective effect of screening endoscopy may last at least 10 years.¹⁵ The risk and rate of progression of SSAs is not as well documented. It has been postulated that the evolution of SSAs to invasive carcinoma may take place in a shorter period of time than the conventional adenoma to carcinoma sequence, but this remains to be firmly established.

Associated Disease States

A number of clinical situations have been associated with a greater than average risk for adenoma development, but the evidence in most cases is tenuous. Although adenomas and carcinomas develop frequently in patients who have undergone urinary diversion by way of ureterosigmoidostomy, this is largely of historical interest. Nonetheless, patients who have undergone this procedure require periodic colonoscopic surveillance for adenoma and carcinoma development. An increased prevalence of colonic adenomas and carcinomas has been reported in patients with acromegaly, and patients with elevated gastrin levels have been reported to be at increased risk for colorectal neoplasia. Alleged associations between colorectal adenomas and a history of prior cholecystectomy, atherosclerosis, acrochordons (skin tags), and HPs remain unproven.

Clinical Features

Adenomatous polyps of the colon and rectum are highly prevalent in Western societies, but most patients with colonic adenomas do not have symptoms directly referable to these lesions. Overt

bleeding manifesting as hematochezia may occur with larger polyps, which may be evident when the polyps are located distally in the rectum. Adenomas typically lose less than 1 mL of blood daily unless they are 2 cm or larger in size. Although colorectal polyps are the most common lesions detected in patients without symptoms undergoing colonoscopy because of the presence of fecal occult blood, the polyps are probably not responsible for the bleeding. Very large colonic polyps may be associated with obstructive symptoms, such as lower abdominal cramping or alterations in bowel habits, but this is unusual. Secretory diarrhea with accompanying hypokalemia and hypochlorhydria has been associated with very large villous adenomas of the distal colon and rectum. This is a rare syndrome, and the search for secretagogues such as vasoactive intestinal polypeptide or prostaglandins in patients with polyps and diarrhea, is infrequently productive.

Adenomas Associated with Lynch Syndrome and Its Variants

Lynch syndrome is a disease of autosomal dominant inheritance in which cancers arise in discrete adenomas, but polyposis (i.e., dozens or hundreds of polyps) does not occur. Lynch syndrome patients can get adenomas, HPs, and sessile serrated polyps (SSPs), but adenoma is the lesion that leads to cancer. The loss of DNA MMR activity usually occurs after the appearance of a small adenoma, and typically occurs after the adenoma is 8 mm or greater in diameter.¹⁶ The mean cumulative number (plus 2 standard deviations) of adenomas in mutation carriers undergoing annual screening colonoscopy is 3 by age 30 and 6 by age 50.¹⁷ However, there are outliers with larger numbers. Currently, the diagnosis of Lynch syndrome is made by finding a germline mutation in the DNA MMR gene, not by clinical criteria.¹⁸ The frequency of Lynch syndrome in the general population is difficult to determine, but Lynch syndrome accounts for about 3% to 4% of all colorectal cancer cases; this suggests that Lynch syndrome may occur in about 2 to 5 per 1,000 of the population.

Turcot syndrome is a term of historical significance, in which there is a concurrence of primary brain tumors and multiple colorectal adenomas or cancer in young people. With the advent of accurate genetic characterization, these families may be categorized as either FAP or Lynch syndrome, as brain tumors are an occasional complication of both diseases, more often a medulloblastoma in FAP, and glioblastomas in Lynch syndrome.¹⁹

Diagnosis

Most colorectal adenomas are asymptomatic and often are detected in the setting of an evaluation for unrelated colonic symptoms or occult blood in the stool. Similarly, adenomatous polyps frequently are detected when patients without symptoms are screened for colorectal neoplasia. Nevertheless, data strongly suggest that the detection and removal of adenomatous polyps are important in reducing colorectal cancer-related mortality.

In 2008, a joint guideline on screening and surveillance for early detection of colorectal cancer and adenomatous polyps was issued by the American Cancer Society (ACS), the U.S. Multi-Society Task Force on Colorectal Cancer (USMTF), and the American College of Radiology (ACR).²⁰ This update of previous guidelines is notable in that it grouped screening tests into those that primarily detect cancer (annual fecal occult blood tests [FOBTs] including those that are guaiac-based or immunochemical, and stool DNA tests, interval not specified) and those that can detect early cancer and adenomatous polyps (flexible sigmoidoscopy every 5 years, colonoscopy every 10 years, double-contrast barium enema every 5 years, or computed tomography [CT] colonography every 5 years). In November 2008, the U.S. Preventative Services Task Force (USPSTF) also issued updated guidelines (Table 67-2).²¹ Based on a targeted evidence-based review and a decision-analytic modeling analysis, the USPSTF recommended screening of average-risk individuals age 50 to 75 years with high-sensitivity FOBTs annually, sigmoidoscopy every 5 years plus FOBTs every 3 years, or colonoscopy every 10 years. Notably, the USPSTF indicated that while the benefits of screening outweigh the potential harms for 50 to 75 year olds, the likelihood that detection and early intervention will yield a mortality benefit declines after age 75 because of the long average time between adenoma development and cancer diagnosis. Routine screening was therefore not recommended for adults aged 76 to 85 years, and screening was not recommended at all in adults older than 85. These guidelines also indicated that for all populations there is insufficient evidence to assess the benefits and harms of screening with CT colonography or fecal DNA testing.

The American College of Gastroenterology (ACG) Guidelines for Colorectal Cancer Screening also grouped options into cancer prevention tests (colonoscopy every 10 years, flexible sigmoidoscopy every 5 to 10 years, and CT colonography every 5 years) and cancer detection tests (annual FOBT with fecal

immunochemical tests [FITs], fecal DNA testing every 3 years).²² Colonoscopy is considered the preferred choice overall. The ACG also recommends that screening in African Americans should begin at age 45 instead of age 50 for average-risk individuals, and that CT colonography replace double-contrast barium enema as a radiologic option. The “European guidelines for quality assurance in colorectal cancer screening and diagnosis” is a 386-page document authored by 90 authors from 32 countries which provides an evidence-based review of existing data on CRC screening which stresses quality measures and cost effectiveness.²³ Numerous international CRC screening programs have been initiated as evidence grows for an impact of CRC screening on mortality.²⁴

Fecal Occult Blood Tests

Screening studies from both Europe and the United States indicate that a polyp is detected in about 30% of patients without symptoms who are 50 years of age or older and undergo colonoscopy for follow-up of a positive fecal occult blood test result. Blood loss from polyps is related to polyp size, and positive fecal occult blood test results are related to polyp size and proximity to the rectum. In one study where rehydrated Hemoccult slides were used (rehydration results in greater sensitivity but also increases the number of false-positive findings), only 15% of polyps smaller than 1 cm were associated with a positive Hemoccult test result, whereas 80% of polyps larger than 2 cm were associated with a positive result. In another study, standard testing with Hemoccult cards detected 17% of adenomas smaller than 1 cm and 42% of adenomas larger than 1 cm. A prospective randomized study of fecal occult blood tests in which rehydrated Hemoccult cards were used indicated that annual testing reduces colorectal cancer-related deaths by 33% through 18 years of follow-up.²⁵ This study, in addition to two European trials, has also demonstrated a 15% to 21% reduction in colon cancer-related death from biennial fecal occult blood testing.²⁶ Thus, unless one rigorously performs the fecal occult blood test on an annual basis, the reduction in colorectal cancer mortality will be disappointing.

Methods that may decrease the false-positive FOBT rates while maintaining or increasing sensitivity currently are being refined and compared for efficiency with Hemoccult-type slide tests. FITs are designed to detect human globin and are not affected by diet or drugs. A variety of FITs are now available worldwide and FIT is likely to replace guaiac-based FOBTs. FITs have good performance characteristics compared with standard heme-based FOBT tests, and may have superior sensitivity and specificity for detecting colonic neoplasms.²⁷⁻²⁹ Issues which remain to be resolved regarding FIT include the optimal number of samples to be tested, requirements for storage and shipping (effect of temperature), and the relative benefit of quantitative (specific amount of hemoglobin per gram of stool) versus qualitative (i.e., positive or negative) reporting, and the optimal “cut-off” for a positive test. The quantitative immunochemical FOBT has been shown to have very good sensitivity and specificity for detection of clinically significant neoplasia in studies of asymptomatic and symptomatic patients, but test performance in prospective screening programs has been less well studied. Recent studies suggest the effectiveness of FIT for programmatic screening for colorectal cancer, but adenoma detection remains much lower than that of carcinoma.²⁹ FITs have now been included as the preferred form of FOBT in screening guidelines.

CLASSIFICATION

Table 67-2 Guidelines for Screening Average-Risk Individuals for Colorectal Cancer

Screening Tool	U.S. Preventive Services Task Force ^a	American Cancer Society, U.S. Multi-Society Task Force, American College of Radiology Joint Guidelines ^b
High-sensitivity FOBT (guaiac based or immunochemical)	Recommended annually as an option	Recommended annually as an option
Flexible sigmoidoscopy + high-sensitivity FOBT q3y	Recommended q5y as an option	Recommended q5y as an option
Colonoscopy	Recommended q10y as an option	Recommended q10y as an option
Double-contrast barium enema	Not recommended as an option	Recommended q5y
Computed tomography colonography	Not recommended as an option	Recommended q5y
Stool DNA testing	Not recommended	Recommended (interval uncertain)

^aU.S. Preventive Services Task Force. Screening for colorectal cancer: US Preventative Services Task Force recommendation statement. *Ann Int Med* 2008;149:627–637. The U.S. Preventative Services Task Force recommends screening for adults age 50 to 75 years. Screening for adults age 76 to 85 is not routinely recommended, and for adults older than 85 years screening is not recommended.

^bLevin B, Lieberman DA, McFarland B, et al. Screening and surveillance for the early detection of colorectal cancer and adenomatous polyps 2008: a joint guideline from the American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology. *CA Cancer J Clin* 2008;58:130–160. Testing options are divided into those that detect adenomatous polyps and cancer (flexible sigmoidoscopy, colonoscopy, double-contrast barium enema, computed tomography colonography) and those that primarily detect cancer (FOBT, stool DNA testing). FOBT, fecal occult blood test.

Figure 67-7. CRC mortality in the National Polyp Study for adenoma and nonadenoma patients with comparison with the US incidence-based mortality rates over up to 20 years. The number of subjects at risk per years followed is given for the adenoma (blue line) and nonadenoma (red line) cohorts. The cumulative incidence-based mortality for the average risk US Population is taken from SEER data (black line). Among patients who had adenomas removed during participation in the study, after a median of 15.8 years, there was a 53% reduction in colorectal cancer mortality compared to expected deaths from colorectal cancer in the general population. (Modified from Zauber AG, Winawer SJ, O'Brien MJ, et al. Colonoscopic polypectomy and long-term prevention of colorectal-cancer deaths. *N Engl J Med* 2012;366:687–696.)

Results from the NPS strongly indicate that the removal of index polyps detected by fecal occult blood testing and other methods, together with subsequent colonoscopic surveillance, results in a very substantial reduction in colorectal cancer mortality. A recent update of this trial with median follow-up of 15.8 years indicated that colonoscopic polypectomy is associated with a 53% reduction in mortality from CRC compared with the expected incidence-based mortality from CRC in the general population (Fig. 67-7).¹⁵

Sigmoidoscopy

The benefit of sigmoidoscopy in interrupting the adenoma-to-carcinoma sequence is suggested by a number of studies. Three prospective randomized trials have now shown that programmatic screening with flexible sigmoidoscopy can have an impact on CRC-related incidence and mortality, mostly related to the detection and removal of adenomas.^{30–32} The UK Flexible Sigmoidoscopy Screening Trial is a randomized trial which tested the hypothesis that a single flexible sigmoidoscopy screening offered at approximately age 60 years can lower the incidence and mortality of CRC.³⁰ In per protocol analyses, the incidence of CRC was reduced by 33% and mortality by 43% (23% and 31%, respectively, based on intention to treat analysis), and the incidence of cancer of the rectum and sigmoid was reduced by 50%. The Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial (PLCO) enrolled 154,900 subjects aged 55 to 74 in a prospective randomized trial that compared flexible sigmoidoscopy with repeat

screening at 3 or 5 years to a usual-care control group.³¹ Flexible sigmoidoscopy reduced CRC incidence by 21% with a benefit observed in both the proximal and distal colon, and reduced overall mortality by 26% (intention-to-treat analyses). Mortality from distal CRC (distal to the splenic flexure) was reduced by 50%, while mortality from proximal CRC was unaffected. The Italian Randomized Controlled Trial (SCORE) demonstrated that once-only sigmoidoscopy significantly reduced CRC incidence by 18% and mortality by 22% (not significant) in intention-to-treat analyses, and by 31% and 38%, respectively in per-protocol analyses (both significant).³² These results have resulted in once in a lifetime flexible sigmoidoscopy being included as an option in the UK National Health Service Bowel Cancer Screening Programme; FOBT is the other option.

Colonoscopy, Barium Enema, Computed Tomography Colonography, and Stool DNA Testing

Colonoscopy may be the most effective tool to screen for colorectal neoplasia (and especially adenomas), but data from prospective randomized trials are lacking. The NPS of polypectomy and surveillance strongly suggested a reduction in colorectal cancer mortality as a result of removing adenomatous polyps compared to historic reference populations. A Canadian population-based study compared the risk of developing colorectal cancer after a negative colonoscopy in all Ontario residents with a history of a complete negative colonoscopy with controls consisting of the Ontario population without a history of colonoscopy.³³ In the negative colonoscopy cohort, the relative risk of distal colorectal cancer was significantly lower than the control group in each of the 14 years of follow-up, while the relative risk for proximal colorectal cancer was significantly lower mainly during the last 7 years of follow-up. A second Canadian case-control study demonstrated that complete colonoscopy was also associated with fewer deaths from left-sided colorectal cancer, but not from right-sided cancer. Several other population-based analyses and analyses of individual screening programs in the United States, Canada, and Europe also suggest that increased use of colonoscopy is associated with mortality reduction from CRC, but this reduction varies by the site of the cancer.^{34–38} A large case-control study using SEER-Medicare data demonstrated that colonoscopy was associated with a 60% decreased risk of CRC-related death, but the association was stronger for distal (OR 0.24; 95% CI: 0.21 to 0.27) than proximal (OR 0.58; 95% CI: 0.53 to 0.64) CRC, consistent with European and Canadian studies.³⁸ These reports suggest that either proximal lesions are not detected as reliably as distal ones at colonoscopy, that the lesions grow at different rates based upon location in the colon, or both.

These findings are of interest in light of arguments that colonoscopy is preferable to sigmoidoscopy, because there may be a substantial incidence of proximal colonic cancers and advanced adenomas beyond the reach of the sigmoidoscope. Some of these individuals may not have distal findings on sigmoidoscopy that would trigger a subsequent colonoscopy. Two trials^{39,40} suggested that approximately 50% of individuals with advanced proximal neoplasms (adenoma > 1 cm; adenoma with villous features or dysplasia; cancer) have no distal neoplasms. Fewer than 2% of those who did not have distal neoplasms, however, had an advanced proximal lesion. A decision analysis commissioned by the USPSTF supports colonoscopy every 10 years as a screening option measured in life-years gained, and the joint guidelines authored by the ACS, USMTF, and ACR recommend colonoscopy as a means of preventing colorectal cancer through adenoma detection and removal.

High-contrast endoscopy using dye or stain solutions combined with colonoscopy (chromoendoscopy) or high-resolution optical methods (e.g., narrow-band imaging and laser confocal endoscopy) have been suggested as a means of identifying lesions in high-risk groups, or as an adjunct to colonoscopy where flat lesions (so-called “flat adenomas”) are suspected. Recent evidence suggests that flat or depressed neoplasms are more common than previously appreciated and carry a high relative risk of containing in situ or invasive carcinoma.⁴¹

Air-contrast barium enema (ACBE) has been included as an option in a variety of screening guidelines, but has for the most part been supplanted by other methods due to its poor sensitivity for detecting small polyps. CT colonography, or “virtual” colonoscopy, involves the use of helical CT to generate high-resolution images of the abdomen and pelvis. CT colonography has the potential advantage of being a rapid and safe method of providing full structural evaluation of the entire colon. Two trials provide evidence that CT colonography may be a valid alternative for primary colon cancer screening. The National CT Colonography Trial⁴² directed by the American College of Radiology Imaging Network (ACRIN) was a multicenter study that employed CT colonography and same-day colonoscopy using a standard matching protocol in 2,600 asymptomatic individuals. Per patient sensitivity of CT colonography for adenomas greater than 10 mm was 90% with a negative predictive value of 99%. A

second trial⁴³ compared CT colonography and optical colonoscopy in parallel screening cohorts and demonstrated similar rates of detection of advanced neoplasia in both groups. Several key issues need to be addressed as the use of CT colonography becomes more widespread, principal among which is determination of the acceptable size cut-off of a lesion detected by CT colonography that will necessitate a follow-up colonoscopy.

A great deal of knowledge has been accumulated recently about genetic alterations that occur during colon carcinogenesis, as discussed earlier. A molecular approach to colorectal cancer screening is therefore attractive since it targets biologic changes that are fundamental to the neoplastic process. Fecal DNA testing relies on the detection of genetic alterations in DNA shed into the stool from neoplastic lesions. Recent prospective data using a multimarker panel which includes both stool DNA testing and FIT showed >90% sensitivity for detecting colorectal cancer, but suboptimal performance for detecting high-risk adenomas. The sensitivity for detection of advanced adenoma with the combined stool DNA marker/FIT panel was 42.4%. FIT alone detected only 23.8% of advanced adenomas.²⁹ Based on these data, the FDA has approved the combined panel for screening for colorectal neoplasia.

Management of Adenomas

Index Polypectomy

Once detected, adenomas should be completely removed, preferably by endoscopic snare polypectomy (Fig. 67-8). Polypectomy is relatively safe and easily performed when adenomas are small or pedunculated. Newer techniques such as EMR and ESD have made it possible to remove even large sessile lesions (Fig. 67-9). Large sessile villous adenomas (>2 cm), especially those with high-grade dysplasia have a great potential for malignant degeneration. If such lesions cannot be completely removed by snare polypectomy or EMR, and when there is uncertainty about the polypectomy margin in the case of pathologically advanced lesions, segmental surgical resection may be necessary. Diminutive polyps, on the other hand, carry little malignant potential. If they are too small for snare polypectomy, ablation with a hot biopsy forceps is a reasonable approach. Because 30% to 50% of patients with one adenoma have a synchronous adenoma elsewhere in the colon, the entire colon should be “cleared” by colonoscopy in polyp-bearing patients.

Figure 67-8. Endoscopic snare polypectomy. **A:** A small colonic polyp. **B:** The polypectomy snare is placed around the polyp. **C:** The snare is closed around the base of the polyp, and the head of the polyp is gently pulled away from the wall and into the lumen. Current is applied to cut the stalk and cauterize the site. **D:** The site after completion of polypectomy.

Quality Measures

As the number of colonoscopies (and colonoscopists) increases, quality assurance measures will need to be adopted. One measure of quality assurance relates to adequate visualization of the colonic mucosa. ADR is defined by the percentage of screening or surveillance colonoscopies of average risk with at least one adenoma and is the most commonly used quality measure in practice. Benchmarks for adequate ADRs have been suggested as at least 15% for women and 25% for men (20% overall). The ADR is

considered by the ASGE/ACG Task Force on Quality in Endoscopy to be the best neoplasia-related indicator of quality performance for screening colonoscopy. The ADR has been demonstrated to be an independent predictor of the risk of interval colorectal cancer after screening colonoscopy.^{44–46} Endoscopist characteristics derived from administrative data are associated with the development of postcolonoscopy colorectal cancer, and have potential use as quality indicators. Other quality measures include the quality of bowel preparation and completeness of polyp resection. The incomplete resection rate in the Complete Adenoma Resection (CARE) study was 10.1% overall, and varied broadly among endoscopists.

Figure 67-9. Endomucosal resection (EMR) of a large sessile polyp. **A:** Large sessile adenoma seen at colonoscopy. **B:** Saline-containing indigo carmine dye is injected into the mucosa to lift the polyp. **C:** The polyp is resected piecemeal using a polypectomy snare. **D:** Completed EMR.

Follow-Up

Much of our current practice has come from information gained through the NPS, first organized in 1978. Additional metachronous adenomas are likely to develop in patients who have had adenomas removed. Colonoscopic surveillance studies have provided estimates of the frequency and time course of recurrence in these patients. Data from the NPS suggested a recurrence rate of 32% to 42% by 3 years after index polypectomy. A prospective colonoscopic analysis also demonstrated a cumulative recurrence rate at 3 years of 42%. Most adenomas detected at this 3-year interval were small tubular adenomas. Age above 60 years, multiple adenomas at index polypectomy and large size of the index adenoma predicted polyp recurrence in the NPS, but only multiplicity predicted recurrence of polyps with advanced pathologic features (i.e., >1 cm, high-grade dysplasia, or invasive cancer) at follow-up. The 3-year recurrence rate in patients with a known history of adenoma (42%) was higher than the incidence rate of adenoma appearance de novo during this period in patients who had no adenomas detected on index colonoscopy (16%).²²

The high recurrence rate of adenomas after index polypectomy supports the use of postpolypectomy surveillance in patients with known histories of adenoma. Colonoscopy is the preferred means of follow-up in these patients. ACBEs are inadequate for surveillance examinations; they miss a substantial

number of large lesions and most small polyps. Barium enema has been supplanted by the use of CT colonography, as discussed earlier. Colonoscopy is the most accurate means of evaluating the colonic mucosa, and most importantly, allows biopsy and removal of polyps.

Several studies, including data from the NPS, indicate that surveillance intervals for colonoscopy should be tailored to risk of recurrence. One recent study examined the relative risk for advanced neoplasia within 5.5 years of a baseline colonoscopy.⁴⁷ There was a strong association between the results of baseline-screening colonoscopy and the rate of serious incident lesions during surveillance. This study confirmed that patients with one or two small tubular adenomas represent a low-risk group compared with other patients with colorectal neoplasia.

Table 67-3 lists the 2012 updated Multi-Society Task Force on Colorectal Cancer guidelines for screening, surveillance, and early detection of colorectal adenomas and cancer for individuals at increased risk or at high risk of disease. This group represents the American Gastroenterological Association Institute, the American Society for Gastrointestinal Endoscopy, and the American College of Gastroenterology. A clinical decision tool based on these guidelines was also published in 2014.⁴⁸ These guidelines suggest that those whose index lesion consists of one or two small tubular adenomas with low-grade dysplasia should have a follow-up colonoscopy no sooner than 5 to 10 years after the initial polypectomy. The precise timing within this interval should be based on clinical factors (prior findings, family history, patient and physician preferences). In those with a large (>1 cm) adenoma, multiple (3 to 10) adenomas, or adenomas with high-grade dysplasia or villous change, colonoscopy should be repeated within 3 years after the initial polypectomy. Although the risk for recurrence of advanced adenomas at this follow-up interval is greater in patients with high-risk adenomas than those with low-risk adenomas, the incremental risk is small.⁴⁹ If the examination is normal or shows only one or two small tubular adenomas with low-grade dysplasia, then the interval for the subsequent examination should be 5 years. Patients with more than 10 adenomas on a single examination should have a follow-up colonoscopy less than 3 years after the initial polypectomy and the presence of an underlying familial polyposis syndrome should be considered. Patients with sessile adenomas that are removed piecemeal should have follow-up colonoscopy in 2 to 6 months to verify complete removal. Guidelines for follow-up of serrated polyps are currently similar to those of conventional adenomas (3 years for lesions ≥ 10 mm, or with dysplasia for TSAs; 5 years for lesions in the proximal colon and without dysplasia; and 1 year for serrated polyposis syndrome).

Table 67-3 Guidelines for the Surveillance of Adenomas in People at Increased or High Risk for Colorectal Cancer

Risk Category	Age to Begin Surveillance	Recommendation	Comment
Increased Risk: Patients with History of Adenomas at Prior Colonoscopy			
Patients with one or two small tubular adenomas with low-grade dysplasia	5–10 yrs after initial polypectomy	Colonoscopy	Precise timing based on clinical factors, patient and physician preferences
Patients with 3–10 adenomas or one adenoma >1 cm or any adenoma with villous features or high-grade dysplasia	3 yrs after initial polypectomy	Colonoscopy	If follow-up examination is normal or shows one or two small tubular adenomas, subsequent examination at 5 yrs
Patients with >10 adenomas on a single examination	<3 yrs after initial polypectomy	Colonoscopy	Consider familial CRC syndrome
Patients with sessile adenomas that are removed piecemeal	2–6 mo to verify complete removal	Colonoscopy	Surveillance individualized based on endoscopist's judgment
Increased Risk: Patients with Family History			
CRC or adenomatous polyps in a first-degree relative before age 60 yrs or in two or more first-degree relatives at any age	Age 40 or 10 yrs before the youngest case in the immediate family	Colonoscopy	Every 5 yrs
Either CRC or adenomatous polyps in a first-degree relative age ≥60 yrs or in two second-degree relatives with CRC	Age 40 yrs	Screening options at intervals recommended for average-risk individuals	Screening should begin at an earlier age, but individuals may be screened with any recommended form of testing
High Risk			
Genetic diagnosis of FAP or suspected FAP without genetic testing evidence	Age 10–12 yrs	Annual FSIG to determine if the individual is expressing the genetic abnormality and counseling to consider genetic testing	If the genetic test is positive, colectomy should be planned
Genetic or clinical diagnosis of Lynch syndrome, or individuals at increased risk of Lynch syndrome	Age 20–25 yrs or 10 yrs before the youngest case in the immediate family	Colonoscopy every 1–2 yrs and counseling to consider genetic testing for inherited DNA MMR	Genetic testing for Lynch syndrome should be offered to first-degree relatives of persons with a known gene mutation. It should also be offered when the family mutation is not known but one of the first three of the modified Bethesda criteria is present.

CRC, colorectal cancer; FAP, familial adenomatous polyposis; FSIG, flexible sigmoidoscopy; MMR, mismatch repair.

Screening and surveillance for the early detection of colorectal cancer and adenomatous polyps 2008: a joint guideline from the American Cancer Society, the Multi-Society Task Force on Colorectal Cancer and the American College of Radiology. *CA Cancer J Clin* 2008;58:130–160; Lieberman DA, Rex DK, Winawer SJ et. al. Guidelines for colonoscopy surveillance after screening polypectomy: a consensus update by the US Multi-Society Task Force on Colorectal Cancer. *Gastroenterology* 2012;143:844–857.

Management of Malignant Polyps

Endoscopic polypectomy is adequate treatment for an adenomatous polyp-containing cancer if it can be demonstrated that the cancer is confined to the head of the polyp (i.e., carcinoma in situ or intramucosal carcinoma; Fig. 67-10). The adequacy of simple polypectomy has been controversial in cases in which malignant cells have invaded the polyp stalk (Fig. 67-11), but most studies indicate that polypectomy is adequate treatment provided that a margin of more than 2 mm is present, the cancer is not poorly differentiated, and no vascular or lymphatic invasion is noted. The presence of cancer at or near the margin is significantly associated with an adverse outcome, even in the absence of other unfavorable parameters. On the other hand, in the absence of unfavorable histology and with a negative margin, the incidence of residual cancer is low (<1%). These criteria are more difficult to assess in sessile polyps. If an adequate margin cannot be demonstrated or negative histologic parameters are present, surgery is recommended to treat the possibility of residual neoplasia or regional lymph node metastases.

Figure 67-10. Diagram representation of cancer-containing polyps. Pedunculated adenoma is described on the left and a sessile adenoma on the right. In carcinoma in situ, malignant cells are confined to the mucosa. These lesions are adequately treated by endoscopic polypectomy. Polypectomy is adequate treatment for invasive carcinoma only if the margin is sufficient (2 mm), the carcinoma is not poorly differentiated, and no evidence of venous or lymphatic invasion is found. (After Haggitt RC, Glotzbach RE, Soffen EE, et al. Prognostic factors in colorectal carcinomas arising in adenomas: implications for lesions removed by endoscopic polypectomy. *Gastroenterology* 1985;89:328.)

Primary Prevention of Adenoma Recurrence

Primary prevention relates to the ability of identifying genetic, environmental, and biologic factors that cause cancer, and to mitigate their outcomes. Laboratory, clinical, and epidemiologic evidence suggests that the regular use of nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, is associated with a substantially decreased risk for the development of colorectal cancer. Four published trials have demonstrated a reduction in adenoma recurrence in chemoprevention trials involving aspirin.^{50,51} Given the biologic plausibility, preclinical in vitro and animal data, and data on adenoma regression in patients with FAP, three large randomized trials, which studied over 6,000 patients in total, were undertaken to examine the effect of cyclooxygenase-2 (COX-2)-selective inhibitors on new adenoma formation in individuals with a history of sporadic adenomas. All of these trials demonstrated a highly significant reduction in new adenoma formation in those taking a COX-2-selective inhibitor (celecoxib or rofecoxib) compared to placebo over 3 years. In the Adenoma Prevention with Celecoxib (APC) trial,⁵² the use of celecoxib was associated with a dose-dependent 33% to 45% reduction in the development of new adenomas by 3 years, with a 57% to 66% reduction in the number of patients developing advanced adenomas. Unfortunately, adverse thrombotic cardiovascular events were associated with COX-2 inhibition in two of these trials. Recent data suggest that increased cardiovascular risk may be associated with most NSAIDs, and not just COX-2 inhibitors.

Other agents currently undergoing study for chemoprevention of colorectal neoplasia include the ornithine decarboxylase inhibitor difluoromethylornithine (DFMO), the bile acid ursodiol, the 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors such as pravastatin and lovastatin, epidermal growth factor receptor (EGFR) inhibitors, and matrix metalloproteinase (MMP) inhibitors. The combination of DFMO and the NSAID sulindac were studied in a randomized placebo-controlled trial to assess their efficacy in preventing sporadic adenoma recurrence in 375 subjects. The use of this regimen was associated with a 70% reduction in new adenomas at 3 years compared to placebo.⁵³ Larger studies are underway to confirm this result and to fully assess toxicity of this combination. A population-based case-control study of individuals with colorectal cancer and matched controls demonstrated a 47% relative reduction of colorectal cancer associated with statin use, but further investigation is needed to assess the overall benefits of this group of agents.

Figure 67-11. Invasive carcinoma in the stalk of an adenomatous polyp. **A:** Low-power view. Malignant glands can be seen invading fibrovascular stalk. **B:** High-power magnification of malignant glands in stalk. Nuclei are large, hyperpigmented, and crowded.

Supplemental calcium reduces proliferative activity in the mucosa of experimental animals and patients at high risk for the development of colorectal cancer. A large body of observational and laboratory studies suggests a role for dietary calcium supplementation in chemoprevention. A prospective, double-blind, placebo-controlled trial showed that supplemental calcium (3,000 mg of calcium carbonate per day, equivalent to 1,200 mg of elemental calcium) reduced the incidence and number of recurrent adenomas in subjects with a recent history of such lesions. The protective effect of calcium supplementation on the risk of colorectal adenoma recurrence extended up to 5 years after cessation of active treatment, even in the absence of continued supplementation.⁵⁴ Analysis of serum vitamin D status in subjects suggested that calcium supplementation and vitamin D status appear to act together to reduce the risk of adenoma recurrence. A prospective trial designed to assess the individual effects of calcium and vitamin D and the combination on adenoma recurrence, however, failed to demonstrate an effect of any of these agents.

“Essential” fatty acids are required for biologic processes, but cannot be synthesized by humans and must therefore be obtained from dietary sources. The main polyunsaturated fatty acids (PUFAs) docosahexaenoic acid (*DHA*, 22:6 Δ 4,7,10,13,16,19) and eicosapentaenoic acid (*EPA*, 20:5 Δ 5,8,11,14,17) are considered “essential” and are obtained predominantly from cold water oily fish such as mackerel and salmon. A randomized trial in subjects with FAP demonstrated that an enteric-coated formulation of EPA has chemopreventive efficacy in reducing rectal polyp burden to a degree similar to that previously observed with selective COX-2 inhibitors.⁵⁵ The role for N-3 PUFAs in “sporadic” colorectal adenoma prevention is currently being evaluated.

Trials of supplemental dietary fiber, as well as antioxidant vitamins such as β -carotene and vitamins C and E, have not convincingly demonstrated any effect on adenoma recurrence.

OTHER MUCOSAL SUBMUCOSAL POLYPS

Hyperplastic Polyps

HPs are small, usually sessile lesions most frequently encountered in the distal colon and rectum (Fig. 67-12A). Although grossly indistinguishable from small adenomas, they carry no significant potential for malignant degeneration particularly when located in the distal colon or rectum. However, HPs must be distinguished from SSAs, which carry significant malignant potential. Macroscopically, HPs are almost always less than 1 cm in size, and most are in the distal colon. In fact, when HPs are found proximal to the rectosigmoid region, one must consider the possibility that this is actually an SSA. Microscopically, HPs are characterized by a saw-toothed epithelial pattern representing micropapillary luminal infoldings of columnar absorptive cells and mature, frequently hyperdistended goblet cells (Fig. 67-12B). Elongation and subsequent infolding of the epithelium may be caused by an expanded, but otherwise normally located, replication zone in the crypt. The cytologic atypia characteristic of adenomatous polyps is not seen in these lesions.

HPs are common age-related lesions found in about one-third of the population older than 50 years. Although they often coexist with adenomas in polyp-bearing patients, no convincing evidence has been found that HPs *per se* are harbingers of adenoma development. Because HPs are asymptomatic and carry

no malignant potential, no specific treatment is required for these lesions. If an HP is the only lesion detected on index-flexible sigmoidoscopy or colonoscopy, no further evaluation is indicated.

Sessile Serrated Adenomas

SSAs or SSPs – the terms are essentially interchangeable – are distinct from conventional adenomas with respect to histology and molecular biology, and are typically nondysplastic in appearance (Fig. 67-5), but may contain areas of dysplasia or intramucosal carcinoma. They are characterized by the serrated appearance of the surface epithelium (common to all serrated lesions), distorted crypt bases and crypt dilation, and by migration of the proliferative zone to the side of the crypt. SSAs represent 3% to 22% of serrated lesions and 75% to 90% of SSAs are right-sided.⁹ They are often flat (>90%), and may be covered by a so-called “mucous cap.” These features often make endoscopic detection difficult, emphasizing the importance of high-quality endoscopy including an excellent bowel preparation and adequate withdrawal times to yield high polyp detection rates. These polyps are thought to be the precursors of sporadic (non-Lynch syndrome) colorectal cancers with MSI, which are overwhelmingly found in the proximal colon.

Figure 67-12. Hyperplastic polyps. **A:** Several diminutive hyperplastic polyps seen in the rectum during flexible sigmoidoscopy. **B:** Photomicrograph of a hyperplastic polyp, characterized by elongated glands with papillary infoldings that have a typical serrated epithelial pattern.

Figure 67-13. Inflammatory polyps. **A:** Severe mucosal inflammation with infiltrates and granulation tissue shown here microscopically can appear clinically with a polypoid configuration. **B:** Resolution of inflammation can leave exuberant polyps covered by normal epithelium, which are called pseudopolyps, a misnomer. These are truly polyps, but are not neoplastic.

Juvenile Polyps

Juvenile polyps can occur sporadically or as part of a juvenile polyposis syndrome (JPS). These mucosal

polyps consist of dilated cystic mucus-filled glands and abundant lamina propria with an inflammatory infiltrate. Seventy-five percent of these occur in children younger than 10 years of age, often appearing as single pedunculated cherry-red polyps with a smooth surface and contour. The exact prevalence of such lesions has not been determined, but they are thought to be acquired lesions detectable in about 2% of children. Juvenile polyps often present with hematochezia because they are highly vascularized lesions. Rectal prolapse and auto-amputation may occur with distal lesions, whereas intussusception may be precipitated by proximal juvenile polyps, particularly in the context of familial syndromes. Individually, these polyps have no malignant potential, but symptomatic polyps should be removed to prevent further complications. Juvenile polyposis, on the other hand, is associated with an increased risk for the early development of cancer.

Inflammatory Polyps

Inflammatory mucosal polyps are common in the setting of idiopathic inflammatory bowel disease. Marked inflammation and ulceration coexist with granulation tissue in a distorted mucosal architecture that appears polypoid because of confluent areas of ulceration, leaving behind islands of intact epithelium (Fig. 67-13A). Subsequent healing leads to the appearance of polypoid, nonneoplastic excrescences covered by normal colonic epithelium, and are called “pseudopolyps,” in spite of the fact that they are truly polypoid excrescences (Fig. 67-13B). They need not be removed and are important largely because they make it difficult to recognize subtle, early neoplastic lesions in these high-risk patients. Severe chronic inflammation of any kind, including a variety of infectious diseases (tuberculosis, amebiasis, schistosomiasis, and amebic colitis), may result in inflammatory polyps that resemble those found in idiopathic inflammatory bowel disease.

Submucosal Polyps

Submucosal masses can expand to push the colonic mucosa into the bowel lumen and thus appear as polypoid lesions. Many submucosal lesions (e.g., lipomas, leiomyomas) are clinically asymptomatic and must be differentiated from neoplastic lesions. Others are malignant lesions that require early detection, such as lymphomas and metastatic tumors. Many submucosal lesions are not detected on endoscopic mucosal biopsy because standard biopsy forceps do not reach beyond the mucosa. If a submucosal lesion is suspected, multiple biopsy specimens of the same site sometimes provide tissue for diagnosis.

Lipomas are benign fatty tumors that occur throughout the gastrointestinal tract but are most commonly found in the cecum near the ileocecal valve (Fig. 67-14). They appear endoscopically as soft, smooth polyps that are pliable and deformable. The overlying mucosa is intact but may be light yellow in appearance. These are benign lesions that have little clinical significance and are more commonly seen in obese patients.

Isolated *lymphoid nodules* consisting of benign lymphoid tissue may appear as sessile smooth polyps of various sizes, with a predilection for the distal colon and rectum. These are usually asymptomatic. Diffuse nodular lymphoid hyperplasia also occurs in children as an incidental finding. The nodules must be distinguished from primary or secondary lymphoma of the large intestine, which may present as mucosal nodularity resembling the pseudopolyposis of inflammatory bowel disease or even a familial polyposis syndrome (Fig. 67-15). Flow cytometry of the lymphocytes in the lesion will be helpful; benign polyposis is polyclonal, whereas lymphomas are monoclonal and may overexpress cyclin D.

Pneumatosis cystoides intestinalis consists of multiple air-filled cysts within the submucosa. This may be an incidental finding in patients with chronic obstructive pulmonary disease, scleroderma, or an asymptomatic pneumoperitoneum secondary to recent surgery or instrumentation, in which air or colonic gas diffuses into the cysts. These sometimes resolve with administration of oxygen. A far more virulent form of pneumatosis is associated with fulminant mucosal inflammation, ischemia, or necrotizing enterocolitis in children. These cysts are thought to result from mucosal invasion by gas-producing bacteria.

Figure 67-14. Submucosal lipomas. **A:** Lipoma seen at colonoscopy. Submucosal fatty tissue causes the mucosa to protrude into the lumen; such protrusion appears as a polyp. Overlying mucosa is smooth. **B:** Lipomatous infiltration of ileocecal valve seen at colonoscopy. **C:** Colectomy specimen showing a large submucosal lipoma cut in cross section.

Figure 67-15. Lymphomatous polyposis of the colon. **A:** Colonoscopic view of B-cell lymphoma presenting as multiple colonic polyps. **B:** Histology of lymphoma is one of the polyps.

Colitis cystica profunda is a rare condition in which the intestinal wall is thickened by submucosal mucus-filled cysts of various sizes and an accumulation of fibroblasts in the lamina propria. It can present as an ulcerating or mass lesion in the rectosigmoid in association with the solitary rectal ulcer syndrome. Although the pathogenesis of this condition is unknown, it may result from the downward displacement of colonic glands during trauma or chronic inflammation followed by healing. The appearance of aberrant submucosal glandular epithelium and acellular mucous lakes must be

distinguished from a colloid or mucinous carcinoma, because this lesion has no malignant potential.

Carcinoid tumors of the rectum appear as isolated, small, yellow-gray submucosal nodules. These are often incidental findings during sigmoidoscopy. Most are smaller than 1 cm, have little malignant potential, and are amenable to local excision. Lesions larger than 2 cm are more likely to be malignant but seldom give rise to metastases. These lesions should be treated aggressively with complete excision. Rectal carcinoid tumors are usually asymptomatic but may present with hematochezia. They are not associated with the carcinoid syndrome. Carcinoid tumors in the proximal colon may be locally invasive or metastasize to the liver, liberating vasoactive peptides into the systemic circulation and producing the carcinoid syndrome.

Other lesions that can present as submucosal polyps include metastatic tumors, such as malignant melanoma, and benign lesions, such as leiomyomas, fibromas, lymphangiomas, hemangiomas, and endometriosis.

GASTROINTESTINAL POLYPOSIS SYNDROMES

Gastrointestinal polyposis indicates the presence of a systemic process that promotes the development of multiple polyps throughout the gastrointestinal tract. In some instances, the polyps are located predominantly in the colon; however, in others, polyps may be found in the stomach, small intestine, colon, and rectum. The classification of the polyposis syndromes has traditionally been based on the histologic characteristics of the polyps, but gradually an awareness of the genetic basis for the most important of these syndromes has permitted more precise diagnosis and rational approaches to treatment.

Familial Adenomatous Polyposis

4 FAP is an autosomal dominant, genetic disease characterized by the development of multiple adenomatous polyps throughout the colon and rectum (Fig. 67-16). The polyps first appear in adolescence, with the median age of onset being about 16 years. The number of polyps in each patient is variable, and they increase in number and size with advancing age. The genetic basis for this disease is an inactivating germline mutation in the *APC* gene. In part, the age of onset, number of polyps, and age at which cancer develops are determined by the location of the mutation in the *APC* gene (Fig. 67-17). Some mutations (located in the middle of the gene) predispose to a very large number of adenomas (>5,000), and other mutations in the first three exons to a smaller number (<100). Additional factors not related to the mutation on the *APC* gene, some genetic and some environmental, also modify the clinical characteristics of the disease.⁵⁶

Figure 67-16. Familial adenomatous polyposis (FAP). **A:** Gross specimen of a resected colon from a patient with FAP. **B:** Sessile and pedunculated adenomatous polyps in the colon of a patient with FAP. **C:** Close-up view of a profuse type of FAP, in which the mucosa is carpeted with innumerable polyps. **D:** Photomicrograph demonstrating profuse FAP with both sessile and pedunculated adenomatous polyps.

Figure 67-17. This scheme of the *APC* (adenomatous polyposis coli) gene illustrates the genotype–phenotype correlations. Most mutations of *APC* result in premature stop codons; therefore, the site of the mutation usually indicates the relative length of the mutant protein product. Mutations at the 5′ end of the gene produce “attenuated” FAP, a milder form of the disease. The retinal lesions (congenital hypertrophy of retinal pigmented epithelium [CHRPE]) occur when the mutations are between exons 9 and 15. The portion of the *APC* gene that binds to other cytoskeletal elements in the cell is represented at the 3′ end of the 15th exon. Mutations in a hot spot immediately downstream from the β -catenin-binding site (between codons 1250 and 1464) result in a more virulent, profuse form of familial adenomatous polyposis. This site is also the location of most of the acquired mutations in sporadic colorectal neoplasms.

Gastrointestinal Features

Polyps in the stomach and small intestine develop in about 90% of patients with FAP. The gastric polyps consist of fundic gland polyps, which are not premalignant lesions. These may appear to be dysplastic, but in the Western world (North America and Europe), gastric cancer is rare. Gastric cancer is a considerable diagnostic problem in FAP in Japan and Korea, however.

Small-intestinal neoplasia is not rare in FAP and principally occurs in the periampullary region of the duodenum. Duodenal adenomatous polyps, which typically appear later than the colonic lesions, may be multiple but tend not to carpet the proximal small intestine. The ampulla of Vater is a particular target

for neoplastic development. With time, carcinoma develops in 5% to 10% of these patients, so that duodenal surveillance is required. Spigelman has developed a classification system that can be used to determine optimal surveillance for duodenal neoplasia, which is based on the number, size, and histologic features of the duodenal polyps (Table 67-4). Adenomas and carcinomas occur in the jejunum and ileum, but these are rare, and routine screening of the small intestine is not recommended. Polyps in the terminal ileum may represent lymphoid aggregates rather than adenomas and should be biopsied for diagnostic purposes.

Classically, it has been stated that the natural history of FAP is for cancer to develop at a median age in the mid-40s. As mentioned, the development of cancer is variable and is based in part on the location of the germline mutation in the *APC* gene. Colon cancer is rather unusual before 30 years of age, and cancer may not develop in patients with the attenuated form of FAP until they are in their 50s or 60s. Cancer occurring in the teenage years has been reported as a result of a patient who had both FAP and Lynch syndrome. Thus, the treatment of these patients relies increasingly on a genetic characterization of the disease.

Extraintestinal Features

Traditionally, patients with manifestations of FAP together with extraintestinal manifestations were considered to have Gardner syndrome. It is now appreciated that families with FAP all have extraintestinal manifestations and that no distinction can be made between families with Gardner syndrome and those with FAP. FAP is characterized by osteomas of the mandible, skull, and long bones and a variety of other benign soft tissue tumors, such as fibromas, lipomas (Fig. 67-18), and sebaceous cysts, which should not be confused with the sebaceous adenomas and carcinomas seen in the Muir–Torre syndrome variant of Lynch syndrome. Osteomas are commonly found in the skull and may be multiple. Some of these lesions have been reported to regress and later reappear. Osteomas may also be found in the mandible, and radiographs of the mouth may reveal impacted or supernumerary teeth. Congenital hypertrophy of the retinal pigmented epithelium (CHRPE) is present in some families with FAP, depending on the location of the mutation in the *APC* gene. CHRPE lesions may be seen in 5% of the general population but are small and usually single. Multiple, bilateral, and large CHRPE lesions strongly suggest FAP. It will require a slit-lamp examination and knowledgeable ophthalmologist to make this diagnosis with confidence, as these are not readily seen in an office ophthalmoscopic examination.

Table 67-4 Spigelman Classification for Management of Duodenal Adenomas in Individuals with FAP

	Points		
	1	2	3
A. Duodenal Disease Grading			
Polyp number	1–4	5–20	>20
Polyp size (mm)	1–4	5–20	>20
Histology	Tubular adenoma	Tubulovillous	Villous
Dysplasia	Mild	Moderate	Severe
B. Recommended Upper GI Surveillance in FAP			
Spigelman stage	Interval to EGD		
Stage 0 (0 points)	5 yrs		
Stage I (1–4 points)	5 yrs		
Stage II (5–6 points)	3 yrs		
Stage III (7–8 points)	1–2 yrs		
Stage IV (9–12 points)	EUS or surgery		

EGD, esophagogastroduodenoscopy; EUS, endoscopic ultrasound; FAP, familial adenomatous polyposis; GI, gastrointestinal.

Figure 67-18. Extraintestinal manifestations of familial adenomatous polyposis (FAP). **A:** Skull film demonstrating osteomas of the calvarium (*arrows*). **B:** Photograph of the mandible demonstrating protuberant mandibular osteomas. **C:** Mandibular radiograph demonstrating a large osteoma of the mandible. **D:** Chest radiograph demonstrating multiple fibromas (*arrows*) in a patient with FAP.

Malignant tumors in the colon are considered to be nearly inevitable in FAP patients, and they may occur occasionally in the duodenum or (less commonly) elsewhere in the gastrointestinal tract. Patients with FAP are also at increased risk for brain tumors, thyroid tumors, adrenal tumors, and malignant tumors of the hepatobiliary tree. Medulloblastomas are a rare complication of FAP, but the risk for this tumor is increased 99-fold in FAP families.

Desmoid Tumors

Desmoid tumors are currently the major cause of mortality and morbidity in FAP (after colorectal cancer) and develop in 10% to 15% of such patients, often as a complication of laparotomy, but sometimes spontaneously. These are benign but aggressive tumors of mesenteric fibroblasts that can encase and obstruct the gastrointestinal tract, arteries, veins, or ureters. They frequently occur in the abdominal wall. In some instances, desmoid tumors can virtually fill the abdominal cavity, and can be lethal. Desmoids are readily visualized on CT of the abdomen, and surgical management of these should be avoided unless they are superficially located. These are more common in women and in those with a positive family history of desmoid tumors.

Genetic Basis of FAP

FAP occurs when a germline mutation in the *APC* gene inactivates the function of the *APC* protein. In most instances, the genetic lesion creates a premature stop codon in the *APC* gene, which in turn leads, to nonsense-mediated decay of the mRNA or the translation of a truncated, nonfunctional *APC* protein. Germline deletions of *APC* also cause FAP. The *APC* gene encodes a large protein (311 kd) that binds to other intracellular proteins – most importantly, the catenins. The *APC* gene encodes 2,843 codons (one for each amino acid) and is broken into 15 translated exons. The structure of the *APC* gene is unique in that the 15th exon makes up about 75% of the coding sequence of the gene. Because it is unusually large, this long, open reading frame is a large target for mutations. This genetic vulnerability probably accounts for the fact that about 25% of mutations in the *APC* occur de novo, in which neither parent carries the mutation, and there is no prior family history of FAP.

The location of the germline mutation is of some clinical significance (Fig. 67-19). For example, mutations that occur at the 5' end of the gene, particularly in the first three exons, result in a clinically mild or "attenuated" form of FAP, in which the number of polyps is smaller and the onset of disease occurs about 10 years later, with cancer developing in the sixth or seventh decade. This occurs because the *APC* gene has an internal ribosomal reentry site downstream of the mutation, which permits the cell to bypass and ignore the premature stop codon. To complicate the situation, family members with the same mutation may have variable manifestations of the disease. Indeed, some members who inherit this mutation have few polyps and no cancer, yet can pass an increased risk for cancer to their progeny.

In contrast, mutations that occur in the "mutation cluster region" of the 15th exon, in a segment between codons 1,250 and 1,464, are associated with a particularly virulent form of the disease, in which the number of polyps is greater than 5,000 and the average age for the development of colorectal cancer is significantly earlier (median age, 34 years). Also, mutations at the extreme 3' end of the gene may be associated with a milder phenotype, with fewer polyps and later onset of cancer. In families who have FAP with CHRPE lesions, the mutations are usually in exons 9 through 15 and only rarely in families whose mutations are in the first 8 exons. Thus, knowledge of the location of the germline mutation can be useful in predicting the clinical manifestations and guide therapy.

Diagnosis

The clinical diagnosis of FAP is usually obvious clinically, but the availability of a genetic diagnosis has changed the approach to this disease. Currently, optimal practice is to obtain a germline diagnosis in an individual who is definitely affected, in order to characterize and counsel the family. A mutation in *APC* can be found in most (90%) of these individuals using commercially available diagnostic laboratories. This will assist in the early and definitive identification of family members who carry the disease-causing mutation and will alleviate anxiety for those who do not. The risk to inherit the mutated gene from an affected parent is 50%, and there is no gender preference. A genetic diagnosis is particularly useful in the attenuated forms of FAP, where the diagnosis is not obvious, and this can help select those family members who need additional surveillance and reassure those who do not. Family members who have the *APC* mutation should begin endoscopic surveillance from their early teens at yearly intervals.⁵⁷

About 25% of patients have FAP that is not present in either parent. This can represent the autosomal recessive form of the disease (*MutYH*-associated polyposis; see later), misattribution of paternity, or phenotypic variation in which a parent actually has a milder form of the disease.

Genetic testing is an essential part of the clinical management of the hereditary cancer, but it can be a challenge. The genetic results are sometimes ambiguous and difficult for the physician to interpret. Additionally, some patients mistake the germline test as a test for cancer. Issues of guilt and denial are prominent in genetic disorders. It is strongly recommended that physicians enlist the involvement of genetic counselors when performing genetic testing and counseling in such patients. The federal "Genetic Information and Non-Discrimination Act" (GINA) protects asymptomatic patients carrying a germline mutation for a serious disease from discrimination in the workplace or with health insurance.

Management

Surgery is the only reasonable management option in FAP, and the clinical decision involves the selection and timing of the operation. The diagnosis of FAP is often made in adolescence, but the development of cancer may not be anticipated for 20 to 30 years after the first polyp appears, depending on the location of the mutation in the *APC* gene. When a child is found to have a germline mutation in *APC*, sigmoidoscopy should begin in the early teenage years, particularly if the mutation is in the "mutation cluster region" or the family's phenotype is known to be associated with thousands of polyps. Ideally, one would like a patient to reach adulthood prior to the colectomy, as the pelvis is larger and the individual is better able to cope with the disease psychologically.

The safest surgical approach is a total proctocolectomy with an ileoanal J-pouch anastomosis. No rectal mucosa should be left behind, since it is at risk for the development of neoplasia. Even with careful endoscopic surveillance of the rectal segment, invasive carcinomas may develop.

The fact that small adenomatous polyps of the rectum can spontaneously regress visibly after a subtotal colectomy and ileorectal anastomosis underscores the reversible nature of the benign adenoma. Additionally, it has been found that adenomas can regress in FAP in response to treatment with sulindac. Several reports have confirmed that even large numbers of polyps regress in patients on 150 to 200 mg of sulindac twice per day. Unfortunately, the polyps reappear when the drug is stopped, and cancer may develop despite treatment with sulindac. Medical treatment is therefore not a safe or reliable first-line treatment for FAP. Furthermore, such treatment may create the illusion of false

assurance of preventing cancer. Sulindac is not effective in the management of upper gastrointestinal tract neoplasia.

Management of Extracolonic Disease. In addition to the risks for colorectal neoplasia, patients with FAP are at risk for the development of osteomas, lipomas, fibromas, and a variety of other lesions. Although these mesenchymal tumors can degenerate into sarcomas, this is a sufficiently rare event that prophylactic surveillance and surgery are not indicated. Likewise, CHRPE lesions do not require treatment. Gastric carcinoma is distinctly uncommon in North American populations where the lifetime risk for gastric cancer in FAP is 0.5%. The bigger problem is that the gastric polyps may look ominous endoscopically and dysplastic pathologically, and one should be reluctant to perform a gastrectomy on a person who has already had a colectomy. Caution is advised when following large gastric polyps in FAP.

The two major management issues after removal of the colon and rectum are periampullary neoplasia and desmoid tumors. One or more adenomas are found in the duodenum in 90% of patients with FAP, usually close to the ampulla of Vater. These lesions should be excised for biopsy and destroyed by electrocautery, laser, or other ablative approaches. Subsequent examination of the upper gastrointestinal tract is guided by the Spigelman criteria (Table 67-4). Complex neoplasms, including adenomas with varying degrees of dysplasia, may require individualized management, including the use of biliary stents while extensive ablative therapy of the periampullary region is performed. Surgical approaches may be required for advanced neoplasms (i.e., carcinoma in situ or invasive carcinoma), but therapeutic endoscopy remains the first option. Duodenotomy with local surgical excision is an option for some of these lesions; occasionally, a Whipple procedure is required for invasive lesions in this region, with low mortality, but considerable morbidity.⁵⁸

Desmoid tumors are aggressive benign tumors of fibroblasts that can cause multiple clinical complications; they are a significant cause of morbidity and mortality in FAP. They typically grow slowly and can surround or compress vascular structures, nerves, or the abdominal viscera. They are more common in women and may be hormonally responsive, so estrogen administration (oral contraceptives or hormone replacement therapy) should be avoided in these patients. Surgical management is generally avoided unless simple local excision of an abdominal wall lesion is possible, and postoperative recurrences are common. Radiotherapy has been used to control the growth of some of these but is generally reserved for superficial lesions. No medical approach to this disease has been uniformly successful. A combination of sulindac plus tamoxifen may be tried for intra-abdominal tumors and has been successful in some patients. Cytotoxic chemotherapy with doxorubicin was successful in a patient whose tumor was refractory to other treatment. Anecdotally, some of these lesions may have *c-kit* mutations and are responsive to imatinib (Gleevec).

Familial Adenomatous Polyposis Variants

5 A number of names, especially *Gardner syndrome*, have been attached to variations of FAP to emphasize the presence of particular extracolonic findings. As mentioned, Gardner syndrome is the same entity as FAP. A few families with prominent sebaceous cysts were historically said to have Oldfield syndrome, and families with brain tumors were said to have Turcot syndrome. All these syndromes represent the variable expression of germline mutations in the *APC* gene and are largely of historical interest. The current mode of classifying FAP families is based on the *APC* gene mutation.

MutYH-Associated Polyposis or MAP

An autosomal recessive form of polyposis has been linked to inheritance of germline mutations in the base excision repair gene *MutYH*, a DNA glycolase.⁵⁹⁻⁶¹ MAP should be considered when multiple adenomatous polyps occur in siblings or in a person who has no vertical family history of polyposis and there is no detectable germline mutation in the *APC* gene. These patients have a relatively mild (attenuated) form of adenomatous polyposis, typically develop 20 to 500 adenomas, and the polyposis is frequently detected in patients 35 to 65 years old. These patients are at very high risk for colorectal cancer, and the disease may present with cancer. The extraintestinal manifestations of FAP, such as duodenal adenomas or CHRPE lesions, occasionally occur but are less common in MAP than FAP. The pathogenesis of this disease is that the germline mutations in *MutYH* permit an excess number of acquired mutations in the *APC* gene (and other genes) to occur in the colon; these mutations are typically G:C → T:A transversions, which is a consequence of losing the DNA base excision repair system. More than 1.3% of the Caucasian population carries a single copy of the *MutYH* alleles Y179C, G396D, and E480X (previously designated Y165C, G382D, and E466X, respectively, but changed due to

renumbering of the coding sequence), and these carriers have a slight increase in colon cancer risk. The Y179C variant has less enzymatic activity than G396D mutation; therefore, homozygotes with Y179C have the most severe phenotype, followed by those with one Y179D and some other mutation, followed by other mutations, which explain the phenotypic heterogeneity in this disease.⁶² Many reference laboratories test for the three commonest *MutYH* mutations on DNA sent from patients with a diagnosis of FAP if there is no detectable germline mutation (or deletion) in *APC*. This strategy is only rational when dealing with European-based mutations. For non-European populations in which this diagnosis is being considered, it is necessary to have the entire *MutYH* gene sequenced. MAP patients can sometimes be managed with frequent colonoscopy when the phenotype is mild, but a colectomy or proctocolectomy may be indicated depending upon the size and distribution of the adenomas, or in patients who choose not to comply with regular colonoscopic surveillance.

Peutz–Jeghers Syndrome

Peutz–Jeghers syndrome is an autosomal dominant familial syndrome associated with multiple gastrointestinal polyps and characteristic skin pigmentation. The gene responsible for this disease encodes a serine/threonine kinase called *LKB1* or *STK11* (Table 67-5); carriers of the gene are highly predisposed to a number of early-onset cancers.

Gastrointestinal Features. The gastrointestinal polyps in Peutz–Jeghers syndrome are nonneoplastic hamartomas consisting of a supportive framework of smooth muscle tissue covered by somewhat hyperplastic epithelium (Fig. 67-20). These are histologically distinct from juvenile polyps and show no inflammatory cell infiltrate. Polyps may be found in the stomach, small intestine, or colon, and in each instance they have a distinctive appearance. Peutz–Jeghers polyps can usually be identified as such by the pathologist, and the characteristic cutaneous pigmentation makes this syndrome readily recognizable.

Table 67-5 Genetic Alterations in Colonic Polyposis Syndromes

Polypsis Syndrome	Chromosome	Gene
Familial adenomatous polyposis (FAP)	5q21	<i>APC</i>
MutYH-associated polyposis (MAP)	1p35	<i>MutYH</i> (recessive)
Peutz–Jeghers syndrome	19p13.3	<i>LKB1/STK11</i>
Juvenile polyposis coli	18q21.1	<i>SMAD4/MADH4</i>
Juvenile polyposis coli	10q22.3	<i>BMPR1A</i>
Juvenile polyposis coli	9q34.11	<i>ENG</i> (endoglin)
Bannayan–Riley–Ruvalcaba syndrome	10q23	<i>PTEN</i>
Cowden disease	10q23	<i>PTEN</i>
Hereditary mixed polyposis (one family)	15q13.3	<i>GREM1</i>

Skin Lesions. The cutaneous manifestations of Peutz–Jeghers syndrome may be found early in life and consist of dark, macular lesions on the mouth (both on the skin and in the buccal mucosa), nose, lips, hands, feet, genitalia, and anus. These lesions tend to become less obvious by the time of puberty. Unlike ordinary freckles, the cutaneous lesions of Peutz–Jeghers syndrome are present from birth. Moreover, ordinary freckles typically do not extend beyond the vermilion border of the lips, nor is the buccal mucosa involved, as it is in Peutz–Jeghers syndrome.

Clinical Complications. The principal complication of Peutz–Jeghers syndrome is intestinal obstruction, which may develop in infancy or childhood. This complication is most prominent in the small intestine because of its narrower diameter. Gastrointestinal bleeding may also be seen in this disease.

Cancer in the small intestine or colon can occur in Peutz–Jeghers syndrome; however, this is an uncommon complication.⁶³ It is thought that neoplasia may arise from foci of adenomatous epithelium found in some Peutz–Jeghers polyps. The risk for cancer is such that prophylactic surgery is not recommended.

Patients with Peutz–Jeghers syndrome are at increased risk for cancers within and outside the

gastrointestinal tract. Cancer developed in about half of the patients in one large study at a median age of about 50 years. At risk are the stomach, small intestine, colorectum, gonads, breasts, pancreas, and biliary tree. Ovarian cysts and sex cord tumors are seen in 5% to 12% of female patients, and boys are at risk for endocrinologically active Sertoli cell testicular tumors that may produce feminizing features before puberty. No internal organ is individually at sufficiently high risk for cancer that a specific screening regimen or prophylactic surgery is indicated. The clinician should be aware of these risks, however, and should be particularly alert to gonadal tumors (which are otherwise rare) and breast cancer (for which screening should start at an early age and bilateral disease should be suspected).

Management. The management of Peutz–Jeghers syndrome is limited to the removal of polyps; endoscopic techniques should be used when possible. Surgery may be required for intussusception caused by small-intestinal polyps. The risk for neoplastic development should be kept in mind, but these patients are not candidates for prophylactic removal of any section of the gastrointestinal tract. As mentioned earlier, gonadal neoplasms and breast cancer are potential complications that may require surgery.

Figure 67-19. Peutz–Jeghers syndrome. **A:** Perioral hyperpigmentation. **B:** Hyperpigmented buccal mucosa. **C:** Gross specimen of a Peutz–Jeghers polyp illustrating a large multilobular lesion. **D:** Low-power photomicrograph of a Peutz–Jeghers polyp of the colon revealing smooth muscle stroma covered by nonneoplastic colonic epithelium. **E:** Photomicrograph of the Peutz–Jeghers polyp at higher power indicates that the stroma contains arborizing bands of smooth muscle.

Juvenile Polyposis

Juvenile polyps are pathologically characteristic lesions that can be solitary or part of a polyposis syndrome. Juvenile polyps are most commonly solitary lesions found in the rectum during childhood. The lesions may be large and are made up of an edematous, mildly inflamed lamina propria covered by normal colonic epithelium (Fig. 67-17). If multiple polyps are found, a familial JPS should be suspected. Three different syndromic presentations have been reported; it is not known, however, whether these are truly distinctive syndromes. They may consist of JPS limited to the colon, JPS throughout the gastrointestinal tract, and JPS limited to the stomach. The genetic basis of this syndrome is not completely understood, but germline mutations in the *SMAD4* (also called the *MADH4* gene) and *BMPR1A* genes each account for about 20% of JPS cases in which the genetic cause can be found.^{64,65} Both these genes are involved in the TGF- β signaling pathway. Also, there are rare cases of patients who have both JPS and hereditary hemorrhagic telangiectasia; these patients typically have mutations in the *SMAD4* gene. Although alterations in the *PTEN* gene were reportedly linked to JPS, germline mutations in this gene are only found in the rare Bannayan–Riley–Ruvalcaba variant, a childhood disorder characterized by macrocephaly, intestinal hamartomatous polyps, and unique pigmented macules of the penis.⁶⁶ Other characteristics include ocular abnormalities, delayed motor development, lipid storage myopathy, and Hashimoto disease. This disorder shares features with Cowden syndrome, which is also caused by *PTEN* mutations.⁶⁷

Figure 67-20. Photomicrograph of a juvenile polyp reveals an attenuated surface epithelium overlying an edematous lamina propria with fluid- and mucus-filled cystic structures.

The manifestations of JPS can vary but are usually limited to bleeding, intussusception, obstruction, and the passage of autoamputated lesions. In some children, a life-threatening protein-losing enteropathy may develop that requires surgical resection of the affected segment of intestine. Patients with familial juvenile polyposis are at increased risk for the development of colorectal cancer and require careful surveillance.

Other Familial Polyposis Syndromes

A variety of other rare syndromes may give rise to multiple gastrointestinal polyps. Cowden syndrome consists of multiple gastrointestinal hamartomas and may be complicated by multiple lesions of the face that arise from follicular epithelium and are pathologically trichilemmomas.⁶⁸ This disease is most often linked to germline mutations in the *PTEN* gene. The diagnosis of Cowden syndrome should be considered for patients with multiple trichilemmomas. Gastrointestinal polyps, which are usually asymptomatic, may develop in these patients. The polyps may include hamartomas, HPs, and ganglioneuromas of the colon. Glycogenic acanthosis of the esophagus may also occur and usually is found incidentally as multiple, diminutive, flat polyps of the esophagus. These patients have an increase in the estimated lifetime risks for the development of breast cancer (85%), thyroid cancer (35%), endometrial cancer (28%), colorectal cancer (9%), kidney cancer (34%), and melanoma (6%).⁶⁹ Cowden syndrome patients should be in the care of someone knowledgeable with these risks. Germline mutations of the *PTEN* gene can be identified in most families with Cowden syndrome.⁷⁰

Other diseases, such as neurofibromatosis (von Recklinghausen syndrome) and the basal cell nevus syndrome, may be associated with multiple gastrointestinal polyps; however, symptomatic complications of these polyps are uncommon.

NONFAMILIAL GASTROINTESTINAL POLYPOSIS SYNDROMES

Multiple gastrointestinal polyps are occasionally seen in nonfamilial syndromes. The Cronkhite–Canada syndrome is an acquired, nonfamilial syndrome characterized by cutaneous lesions (Fig. 67-21), chronic diarrhea, protein-losing enteropathy, and gastrointestinal polyps. The enteropathy may produce progressive inanition and dehydration that can result in death. The diarrhea is attributable to diffuse mucosal injury of the small intestine but may be complicated by bacterial overgrowth. Gastrointestinal polyps are present in most patients and occur in the stomach, small intestine, colon, and rectum. These polyps are pathologically similar to juvenile retention-type polyps. The lamina propria is edematous and contains an inflammatory infiltrate. As has been reported in juvenile polyps, the lesions in this syndrome may contain adenomatous epithelium, and occasionally carcinomas have complicated this disease, but this is not a usual feature of the disease. A variety of medical and surgical measures have been used as treatment, and primary attention should be drawn to the treatment of the diarrhea and maintenance of the nutritional status. The cutaneous lesions consist of onycholysis, alopecia, and hyperpigmentation. Multiple therapeutic approaches have been tried, including broad-spectrum antibiotics, steroids, antihistamines, and extended bowel rest with parenteral nutritional support. Each approach has had occasional success, but none is uniformly effective. The disease is more common in Asia than in North America or Europe. Curiously, the cutaneous features may resolve despite persistence of the gastrointestinal polyps.

Figure 67-21. Cronkhite–Canada syndrome. Onycholysis and hyperpigmentation are characteristic cutaneous manifestations of Cronkhite–Canada syndrome, a nonfamilial, poorly understood, and acquired condition in which multiple juvenile, inflammatory-type gastrointestinal polyps and characteristic cutaneous features are found.

Other acquired lesions that may present with multiple gastrointestinal polyps include inflammatory pseudopolyps in the setting of inflammatory bowel disease, lymphoma, pneumatosis cystoides intestinalis, and multiple lipomas or HPs. None of these syndromes requires specific surgical treatment.

Chapter 68

Colorectal Cancer

Julio Garcia-Aguilar

Key Points

- 1 Incidence and overall mortality for colorectal cancer (CRC) are decreasing, most likely due to increased screening. Risk-factor modification and improved therapy also likely contribute to this trend.
 - 2 Our greater understanding of the molecular biology of CRC may provide a means of identifying disease biomarkers and developing more targeted therapies.
 - 3 Advances in imaging techniques have improved risk stratification via more accurate baseline tumor staging and treatment selection.
 - 4 Improved risk stratification and neoadjuvant therapy have enabled physicians to eliminate some therapeutic components in some patients' treatment regimens.
 - 5 Use of laparoscopic and robotic surgical techniques in combination with enhanced recovery programs has accelerated patient recovery, reduced length of hospital stay, and reduced postoperative complications.
 - 6 While long-term survival for patients with stage IV disease remains low, median survival for these patients has improved significantly in recent years, probably due to more effective chemotherapy and more aggressive surgery.
 - 7 Multidisciplinary treatment involving surgical oncologists, medical oncologists, radiation oncologists, as well as liver surgeons, gastroenterologists, and stoma therapists improves outcomes and quality of life in patients with CRC.
-

Colorectal cancer kills tens of thousands of people every year in the United States. If diagnosed at an early stage, however, it is one of the most curable malignancies. Identification of populations at risk and screening of asymptomatic patients are therefore crucial imperatives. This chapter provides a comprehensive overview of the disease, including epidemiology, risk factors, molecular characteristics, progression, staging, screening, diagnosis, and treatment.

EPIDEMIOLOGY

1 Colorectal cancer (CRC) is the third most common malignancy and the second most common cause of cancer death in the United States. It is estimated that in 2015, a total of 132,700 people were diagnosed with CRC in the United States, and 49,700 died from the disease.¹ Approximately 1 in 20 Americans will be diagnosed with CRC in their lifetime. Death from CRC could be reduced significantly by applying current knowledge about screening, early diagnosis, and treatment standards. The incidence and mortality rates for CRC have been decreasing for the last three decades, but the decreases have accelerated since 2001 ([Fig. 68-1](#)). Between 2007 and 2011, the incidence of CRC decreased at a rate of 3.6% for both genders, and mortality at a rate of 2.6% in males and 3% in females. The declines in incidence and mortality have been attributed to the detection and removal of precancerous polyps as a result of CRC screening programs, changing patterns in CRC risk factors, and improvements in treatment.

The incidence and mortality rates for CRC increase with age. The median age at colon cancer diagnosis is 69 years in men and 74 years in women; for rectal cancer, 63 in men and 65 in women. More than 90% of CRCs are diagnosed in patients 50 years or older. Both the incidence and mortality for CRC are 30% to 40% higher in men than in women. The reasons for these differences are not completely understood but probably reflect an interaction between risk factors and hormonal differences. There are also gender differences in the distribution of CRC, with a higher proportion of

proximal tumors in women.

There are great disparities in CRC incidence and mortality between ethnic and racial groups. Both are highest for African Americans and lowest for Asians/Pacific Islanders, but the differences in mortality are proportionally larger compared to the differences in incidence. The decline in mortality for CRC that began in the 1980s did not start affecting African Americans until the 1990s. These differences are attributed to disparities in access to screening and care. The decline in CRC-related mortality among African Americans has also accelerated in recent years.²

CRC is the third most common cancer in men and the second most common cancer in women worldwide, with an estimated 1.4 million new cases diagnosed in 2012 (Fig. 68-2). It is responsible for 8% of cancer deaths worldwide. The age-standardized incidence of CRC varies significantly in different countries. It is highest in North America, New Zealand, Australia and Western Europe and lowest in India and many African countries. While the incidence is decreasing in some developed countries (United States) and stabilizing in others (France, Australia), it is increasing in Asia (Japan) and the Middle East (Kuwait), Eastern European countries (Czech Republic, Slovakia, Slovenia), and some Southern European countries (Spain). The increase in incidence has been attributed to changes in risk factors, such as the Westernization of diets, obesity, and smoking. However, despite the increase in incidence, mortality for CRC is decreasing in many countries, most likely because of improvements in both screening and treatment.²

RISK FACTORS

There are numerous factors associated with the risk of CRC (Table 68-1).³ Some are behavioral, and potentially modifiable. Others are genetic or hereditary, and therefore nonmodifiable. Information about individual risk factors can be used to reduce incidence and mortality through behavior modification and screening programs.⁴ Except for the relatively uncommon hereditary syndromes with known patterns of inheritance, the relative contribution of inherited and environmental factors to the development of CRC is controversial. Analysis of cohorts of twins from Scandinavian countries suggests a significant but relatively minor contribution of hereditary factors to the development of sporadic CRC; the environment seems to play a larger role in the development of sporadic cancers.⁵

Figure 68-1. Trends in Colorectal Cancer Incidence and Death Rates by Sex, USA, 1930–2010. (From The American Cancer Society, Colorectal Cancer Facts and Figures 2014–2016.)

The list of behavioral or modifiable factors includes obesity, physical inactivity, smoking, diet, and alcohol intake.⁶ Obesity is associated with increased risk of developing CRC in both men and women.^{7,8} Abdominal obesity, measured as waist size, seems to be more important than excess weight, particularly in men. Being overweight increases the risk of CRC, independent of the level of physical activity. The most physically active people have a 25% lower risk of developing CRC, compared to the least active people. Both recreational and occupational physical activity reduces CRC risk, and sedentary people who become physically active later in life do reduce their CRC risk.⁹ The geographical differences in the incidence of CRC, and the change in incidence in migrant populations, suggest that diet is probably an important risk factor.¹⁰ The risk of CRC has been associated with a high consumption of red or processed meats.^{11,12} On the other hand, the risk of CRC is inversely correlated with the intake of fiber and whole grains, fruits and vegetable, dairy products and calcium, vitamin D, and folates.⁶ Alcohol

consumption is causally associated with the development of CRC, and the effect seems to be dose-dependent. The risk seems to be higher for men than for women. There is no difference in the effect with regard to the type of alcohol.¹³ Smoking increases the incidence and mortality from CRC, and in particular, rectal cancer.^{14,15}

Table 68-1 Factors Associated with Risk of Developing Colorectal Cancer

Factors That Increase Risk
<i>Behavioral, Modifiable</i>
Heavy EtOH use (2–4 drinks/day)
Obesity
Red or processed meats
Smoking
Physical inactivity
<i>Hereditary, Nonmodifiable</i>
Hereditary Polyposis and Nonpolyposis Syndromes
Family History
First-degree relative with CRC
Multiple relatives with CRC
Relative diagnosed with CRC before age 45
<i>Medical History</i>
Inflammatory bowel disease (Crohn disease, ulcerative colitis)
Diabetes
Factors That Decrease Risk
Physical activity
Dairy
Fruit and vegetable

Vitamin D and folates

Three-quarters of CRCs occur in people who do not have any particular predisposing factors, and who are therefore considered to be at average risk. The remaining 25% of patients have hereditary risk factors that predispose them to the development of CRC: either a well-defined hereditary CRC syndrome (5%) or a close relative who has been diagnosed with the disease (20%). People with a first-degree relative with CRC have between a 1.9 and 4.4 relative risk of developing CRC, compared to the average population. The risk is higher when the affected relative was diagnosed at an early age, or when several relatives have been affected.^{16,17} CRC survivors have four times the lifetime risk of developing a new (metachronous) CRC, compared with people at average risk. The estimated mean annual incidence of metachronous CRC is 0.3%, with a cumulative incidence of 3.1% at 10 years.¹⁸ A personal history of adenomatous colorectal polyps also increases the risk of CRC, in particular for patients with larger or multiple polyps and an early age at diagnosis.¹⁹

Patients with chronic inflammatory bowel disease, both ulcerative colitis and Crohn disease, are at increased risk of developing CRC.^{20,21} The risk increases with the duration of the disease. It is estimated that, after 10 years of disease, the risk of developing CRC increases by around 1% each year. Thus, it is estimated that patients with 30 years of inflammatory bowel disease have an 18% risk of developing CRC. The risk is higher for patients diagnosed with inflammatory bowel disease at an early age, and with disease extending proximal to the splenic flexure. However, the incidence of CRC in patients with ulcerative colitis seems to be decreasing. A recent meta-analysis of population-based cohort studies reported a 1.7 increased risk of CRC among inflammatory bowel disease patients, compared to the general population, after adjusting for age, gender, and duration of disease.²² These changes are probably due to more effective treatments and the efficacy of surveillance programs.²³

Figure 68-2. Estimated New Cancer Cases and Deaths Worldwide for Leading Cancer Sites by Sex and Level of Economic Development, 2012 (excluding nonmelanoma skin cancers). (From Torre LA, Bray F, Siegel RL, et al. Global Cancer Statistics, 2012. *CA Cancer J Clin* 2015;65:87–108.)

Figure 68-3. Mutation frequency across 224 human colorectal cancer samples from The Cancer Genome Atlas. Note the clear separation of hypermutated (median of 728 nonsilent mutations per tumor) and nonhypermutated (median of 58 nonsilent mutations). Red, MSI high, CIMP high, or MLH1 silenced; light blue, MSI low, or CIMP low; black, rectum; white, colon; gray, no data. (From Comprehensive Molecular Characterization of Human Colon and Rectal Cancer. The Cancer Genome Atlas Network. *Nature* 2012;487(7407):330–337.)

Patients with type II diabetes have a higher risk of developing CRC compared to the nondiabetic individual, even when adjusting for factors such as obesity and sedentary lifestyle.²⁴ In addition, CRC survival rates are lower for diabetic patients compared to nondiabetic patients.²⁵ The relationship between diabetes and CRC seems to be stronger for men than for women.

MOLECULAR CHARACTERISTICS

2 The traditional model of CRC tumor development is often represented as a linear and sequential progression from normal epithelium to small adenoma, to large adenoma, to invasive carcinoma, and finally to metastatic disease.²⁶ This so-called adenoma–carcinoma sequence has been deemed the result of the progressive accumulation of alterations in the genome. This model has shaped our understanding of key genetic alterations that result in colorectal tumorigenesis, and has had an enormous clinical impact by highlighting the importance of screening and surveillance. Whole genome analysis with high-throughput technologies has added new information that is broadening our understanding of colorectal carcinogenesis. Every CRC has a multitude of distinct genetic alterations that perturb a number of molecular pathways. This genetic heterogeneity ultimately has a bearing on the speed of growth, local invasiveness, metastatic potential, and response to therapy. As our understanding of these molecular changes improves, we anticipate that we will be able to provide better screening and prognostic tools, and discover new tumor-specific therapies.

The most comprehensive molecular analysis of CRC to date has been conducted by The Cancer Genome Atlas Consortium.²⁷ They have used state of the art technology to elucidate the mutational spectrum, the chromosomal and sub-chromosomal changes, the epigenetic regulation and transcriptional alterations in a large number of CRCs. A key finding that has helped frame our molecular understanding of CRC is the wide variation in the number of somatic mutations present in most tumors. According to the number of mutations, CRC can be effectively classified as hypermutated, harboring a median of 728 nonsilent mutations per tumor, and nonhypermutated, with a median of 58 nonsilent mutations (Fig. 68-3). Nonhypermutated tumors comprise 84% of CRCs, and are characterized by chromosomal instability (CIN). CIN is the result of missegregation of chromatids in tumor cells, resulting in gains and losses of entire chromosomes or chromosomal segments; manifesting as aneuploidy and copy number alterations (CNA).²⁸ Common patterns of aneuploidy and CNAs in nonhypermutated CRC include amplifications in chromosome arms 1q, 7p and q, 8q, 13q, 17q, and 20p/q, and deletions in 8p, 14q, 15q, 17p, and 18p/q. Some of these CNAs could account for the loss of important tumor suppressors such as TP53 (on 17p), DCC, and SMAD4 (on 18q), and the amplification of oncogenes such as ERBB2 (on 17q). In short, CIN in nonhypermutated tumors can activate critical oncogenes, and inactivate tumor suppressors that contribute to the acquisition of tumorigenic traits.

The hypermutated tumors, representing 16% of all CRCs, are deficient in the mismatch-repair (MMR) mechanisms controlling the correction of errors that occur during DNA replication. The end result of MMR deficiency is a form of genetic instability characterized by the accumulation of mutations throughout the genome, primarily in repetitive sequences known as microsatellites; this is known as microsatellite instability (MSI).²⁹ The mutational burden ultimately provides these MSI tumors with their malignant potential. Unlike CIN tumors, MSI tumors generally remain diploid or near-diploid. They are less likely to have KRAS, TP53, SMAD4 mutations, and more likely to have BRAF and TGFBR2 mutations (Fig. 68-4). MSI can arise from either the germline inactivating mutations or the epigenetic silencing of one of several MMR genes (MLH1, MLH3, MSH2, MSH3, and MSH6). Research into the mechanisms of epigenetic silencing of MSI tumors has helped elucidate the CpG Island Methylator Phenotype (CIMP), whereby the methylation of CpG sequences in the promoter region of MMR genes (most commonly MLH1) leads to their transcriptional silencing.

The classification of CRC according to the type of genomic instability is clinically relevant. MSI tumors tend to be preferentially right sided, have a solid or cribriform histologic pattern, contain large number of tumor-infiltrating lymphocytes, are less responsive to fluoropyrimidine, and in general carry a better prognosis, compared to CIN tumors.

The genomic instability that characterizes CRC is associated with alterations in a number of key pathways; among others, the WNT, MAPK, PI3K, TGF- β and p53 pathways (Fig. 68-5). The WNT signaling pathway contributes to the tightly regulated homeostasis of intestinal epithelial crypts, and its alteration is considered an initiating event in colorectal carcinogenesis. The WNT signaling pathway is altered in greater than 90% of both hypermutated and nonhypermutated CRCs. The most prevalent alteration leading to dysregulation of the WNT pathway occurs through biallelic inactivation of the tumor suppressor adenomatous polyposis coli (APC) gene.³⁰ Patients with familial adenomatous polyposis (FAP) have a germline mutation in one allele of the APC gene, and their risk of developing CRC is virtually 100%. The WNT pathway is also commonly altered as a result of stabilizing mutations of the CTNNB1 gene coding for β -catenin, a protein normally targeted for degradation by APC. The accumulation of β -catenin as a result of APC loss or stabilizing CTNNB1 mutations leads to its translocation to the nucleus, where it interacts with transcription factors of the TCF/LCF family, turning them into transcriptional activators. The end result is an increase in the transcription of genes that are normally important for stem cell renewal and differentiation but, when inappropriately expressed at high levels, can cause cancer.

Figure 68-4. Most significantly mutated genes in hypermutated and nonhypermutated tumors. Blue bars represent genes identified using the MutSig algorithm, and black bars represent genes identified by manual examination of sequence data. (From Comprehensive Molecular Characterization of Human Colon and Rectal Cancer. The Cancer Genome Atlas Network. *Nature* 2012;487(7407):330–337.)

Mutational inactivation of the TGF- β pathway, important in regulating cell growth arrest and apoptosis, is a common event in CRC.³¹ In the majority of hypermutated tumors, the TGF- β gene is inactivated by a frameshift mutation in a polyadenine repeat within the coding sequence. It can also be inactivated by point mutation in the kinase domain. Downstream effectors of this pathway such as the transcription factor SMAD4, and associated proteins SMAD2 and SMAD3, are also inactivated by mutation or homozygous deletion of chromosomal segment 18q. Another member of this pathway, deleted in CRC (DCC), is also commonly inactivated by deletion of chromosome 18q.

Figure 68-5. Frequency of genetic changes leading to deregulation of recognized signaling pathways in CRC. Alterations are defined as somatic mutations, homozygous deletions, high-level focal amplifications, and in some cases, significant up- or downregulation of gene expression. Red/blue denote activation/inactivation, respectively. Bottom panel shows alterations across samples in five main pathways (WNT, TGF-β, RTK/KRAS, PI3K, TP53, if at least one gene in the pathway is altered). nHM, nonhypermutated; HM, hypermutated. (From Comprehensive Molecular Characterization of Human Colon and Rectal Cancer. The Cancer Genome Atlas Network. *Nature* 2012;487(7407):330–337.)

A common theme of the WNT and TGF-β signaling pathways is the increased activity of c-Myc, a regulator gene that codes for a multifunctional transcription factor which plays a role in cell cycle progression, apoptosis, and cellular transformation. c-Myc seems to play a central role in colorectal carcinogenesis.³²

The TP53 gene is a member of a pathway of regulators of cell cycle arrest and cell death in response to a variety of genotoxic stresses. Mutations in the TP53 tumor suppressor gene occur in more than half of nonhypermutated CRCs. In most tumors, both alleles of the gene are inactivated by a combination of a mutation in one allele, and loss of the second allele by deletion of the chromosomal segment 17p. Loss of the TP53 tumor suppressor gene is generally considered an early event that plays a role in the transition from adenoma to invasive carcinoma.³³ In hypermutated tumors, the TP53 pathway may be attenuated by mutations in other genes, such as the proapoptotic BAX.

The MAPK pathway consists of a cascade of tightly coordinate kinases that work together to regulate cell division and proliferation. KRAS, a protooncogene that becomes constitutively activated by mutation, resulting in uncontrolled cell proliferation, is mutated in 37% of CRC. Interestingly, a number of studies from model organisms reveal that KRAS mutation by itself is not sufficient to initiate tumorigenesis; in order to have oncogenic potential it requires a previous APC mutation. The MAPK pathway is the molecular pathway that has successfully been therapeutically targeted in CRC. Inhibition of this pathway using antibodies against the epidermal growth factor receptor (EGFR) reduces progression in wild-type KRAS/NRAS metastatic CRC.³⁴ Activating mutations of BRAF, also an effector member of the MAPK pathway downstream of KRAS, are seen in 13% of CRC. The BRAF mutation, found almost exclusively in hypermutated tumors, has been associated with poor prognosis.

The PI3K/AKT/mTOR signaling pathway, with important roles in cell proliferation and apoptosis, is abnormally activated in nearly half of all CRCs. Moreover, in the TCGA cohort, PI3K and RAS pathways are simultaneously affected by mutations in one-third of all CRCs, suggesting that simultaneous inhibition of both pathways may be required to achieve a therapeutic effect.³⁵

The characterization of genome-level alterations in CRC has led to the identification of new sub-classifications that share marked similarities across genomic structure, gene and protein expression, and even the activity of the tumor microenvironment.^{36–39} While these sub-classifications continue to be

resolved and studied, they have shown potential to prognosticate tumor behavior and oncologic outcomes.⁴⁰

The advances in genomic characterizations have revealed CRC to be a heterogeneous and complex disease. While the patterns of genomic instability and alterations of signaling pathways are aligned with specific phenotypic tumor characteristics, many tumors do not fit cleanly into any single category. Rather, they may host elements of genomic instability and dysregulated signaling pathways that may not be well characterized yet.

HISTOPATHOLOGY AND PROGRESSION

CRC is an adenocarcinoma arising from the epithelial lining of the large bowel. Some CRCs may develop de novo, but most result from malignant transformation of adenomatous polyps. In the past, only tubular and villous adenomas were considered to develop into invasive adenocarcinomas. However, recent evidence suggests that serrated polyps can also develop into CRCs. Polyps arise from normal mucosa, and gradually increase in size. Some polyp characteristics – size larger than 1 cm, tubulovillous or villous histology, multiple occurrences – are associated with a high risk of malignant transformation. Most screening programs are designed to recognize the presence of polyps, or early malignant change in polyps or the surrounding mucosa.

HISTOPATHOLOGIC TYPES OF COLORECTAL CANCER

Table 68-2 Colorectal Cancer: Histopathologic Types

Carcinomas
Adenocarcinoma
Medullary carcinoma
Mucinous adenocarcinoma (greater than 50% mucine content)
Signet ring cell carcinoma (greater than 50% signet ring cells)
Neuroendocrine adenocarcinoma
Squamous cell carcinoma
Adenosquamous carcinoma
Small cell carcinoma
Undifferentiated carcinoma
Other Tumors
Carcinoid
Lymphoma
Sarcomas

The majority of CRCs are typically adenocarcinomas that form glandular structures resembling the normal colonic epithelium. However, there are several histologic types of adenocarcinoma (Table 68-2). Colorectal adenocarcinomas are assigned to one of four histologic grades according to their histologic resemblance to the normal colonic epithelium (Table 68-3). The histologic grade is associated with oncologic outcome independent of other risk factors, including tumor staging.

CRC is locally invasive, potentially spreading through the full thickness of the bowel wall into adjacent tissues. From the primary site, CRC often extends to the regional lymph nodes and to other organs. CRC can metastasize to almost any organ, but the most common sites are the liver and lungs. Approximately 20% to 34% of patients have metastases at the time of diagnosis, and another 30% of those initially treated with curative intent will subsequently develop distant metastases. Other sites of distant metastasis are the brain and bones, but these are unusual in the absence of liver metastases. Patients may also develop peritoneal spread, with the formation of malignant ascites. The risk of nodal metastasis increases with the depth of tumor invasion into the bowel wall, and the risk of distant metastasis is higher for patients with nodal metastasis.

STAGING AND PROGNOSIS

The anatomical extent or stage of the tumor at the time of diagnosis is a key factor in deciding upon

treatment and defining prognosis in patients with CRC. The tumor–node–metastasis (TNM) classification developed by the UICC/AJCC is firmly established as the preferred staging system (Table 68-4). It classifies CRC according to the extent of the primary tumor (T), the involvement of the regional lymph nodes (N), and the presence or absence of distant metastasis (M). The TNM classification is important for both clinical and pathologic staging. Most colon cancers, and many rectal cancers, are staged after surgery and pathologic examination of the surgical specimen (pTNM). Many rectal cancer patients, and a small but growing number of colon cancer patients, do not receive surgery as the initial therapy, which makes clinical TNM (cTNM) staging based on medical history, physical examination, endoscopy, and imaging, increasingly important. As tumors experience a variable degree of regression with preoperative chemotherapy and/or radiation, it is important that patients receiving neoadjuvant therapy are assigned an accurate cTNM stage before starting treatment. For patients who have received neoadjuvant therapy, a modified pathologic staging is generated after surgical resection, annotated by the prefix y (ypTNM). The 7th edition of the AJCC Cancer Staging Manual incorporates a four-tier tumor regression grading (TRG) system for patients receiving neoadjuvant therapy. In this grading system TRG 0 represents Complete Response, no viable tumor cells or complete pathologic response (pCR); TRG 1, Moderate Response; TRG 2, Minimal Response; and TRG 3, Poor Response. Tumor regression seems to correlate closely with prognosis and long-term oncologic outcome.⁴¹

HISTOLOGIC GRADE

Table 68-3 Histologic Grading

G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated
GX	Grade cannot be assessed

The AJCC staging system is updated periodically in response to newly acquired clinical data and understanding of the biology of the tumor. The 7th edition of the AJCC Cancer Staging Manual, for all cancers diagnosed after January 1, 2010, was updated based on observed survival outcomes obtained from the National Cancer Institute’s Surveillance, Epidemiology, and End Results (SEER) program.⁴² Relative survival in CRC patients decreases according to the depth of tumor penetration into the bowel wall and number of lymph nodes involved, but the presence of distant metastasis is the single most important predictor of survival in these patients (Table 68-4). Other tumor and treatment-related prognostic factors, in addition to the TNM stage, are listed in Table 68-5.

Quantitative parameters of lymph node evaluation – number of positive lymph nodes, total number of lymph nodes examined, and lymph node ratio – have prognostic implications in CRC. The number of nodes involved by tumor is included in the N category of the TNM system. The current staging system recommends examining a minimum of 12 lymph nodes for adequate staging.⁴² The total number of lymph nodes retrieved is lower in rectal cancer patients treated with preoperative chemotherapy and radiation, but the minimal number of nodes required for adequate staging in these patients is unknown. The total number of nodes examined has an important impact on outcome in patients with colon and rectal cancer; in patients with all T and N combinations, the probability of survival increases linearly with the number of lymph nodes examined. The lymph node ratio, defined as the number of positive lymph nodes divided by the total number of retrieved nodes, has also been considered an independent predictor of survival.^{43,44} However, the results have not been extensively validated and the lymph node ratio is not currently included in staging. Irregular tumor deposits in the mesocolon or mesorectum without surrounding lymph node tissue, are considered peritumoral tumor deposits; they are not counted as lymph nodes but are classified as N1c, and contribute to stage III.⁴² These are considered to represent large vessel or perineural invasion. The significance of micrometastasis detected by immunohistochemistry (usually with anticytokeratin antibodies) in H&E negative nodes of patients with stage II disease is controversial. Although some studies have reported an association between micrometastasis, increased recurrence and reduced survival, the detection of micrometastasis has not been incorporated into clinical practice, and at the present time should be considered investigational.^{45,46}

The location of the tumor also provides prognostic information. In general, tumors located in the right colon have better prognosis compared with tumors located in the left or transverse colon. This

may be attributed, in part, to the higher proportion of MSI tumors in the right side of the colon. In patients with rectal cancer, tumors located in the distal rectum have worse prognosis compared to tumors located in the upper rectum.

The quality of the surgery and the completeness of tumor resection also provide important prognostic information. The distance of tumor to the circumferential resection margin (CRM) – defined as the surgically dissected nonperitonealized surface of the specimen – provides important prognostic information in both colon and rectal cancers. The presence of tumor at the CRM, because of advanced stage or inadequate resection, is associated with a high rate of recurrence and decreased probability of survival. In rectal cancer patients, the CRM is defined as positive if the tumor, either by direct tumor extension or positive lymph node, is equal to or less than 1 mm from the resection margin.

The AJCC has established codes for completeness of the resection, which should be reported for each procedure.⁴² A resection is defined as R0 when the entire tumor is resected and the margins are histologically negative; R1 when the margins are grossly uninvolved but histologically positive; and R2 when the tumor is not completely resected, and there is gross residual tumor at the primary site, regional lymph nodes, or metastatic sites.

Other factors associated with worse outcomes include elevated CEA levels before surgery, high histologic grade, signet ring cell and small cell histopathologic type, lymphatic and blood vessel invasion, and perineural invasion.^{47–52} Vascular invasion is considered a sign of aggressive behavior in CRC, and has been associated with a higher risk of disease progression and poor prognosis. Capillary invasion is often associated with lymphatic invasion, and these are commonly designated as lymphovascular invasion. Large vessel invasion, detectable on magnetic resonance imaging (MRI), is now reported separately.

While the TNM staging system provides important prognostic information, it is inadequate for individual prognostication. Outcomes for individual patients within each tumor stage are variable. Recently, nomograms using a number of clinical and pathologic characteristics have been designed to improve prediction and survival beyond TNM staging in patients with colon or rectal cancer, particularly in the setting of stage II tumors (Fig. 68-6).⁵³ In addition to providing prognostic information, nomograms may potentially guide clinical decisions, such as the use of adjuvant chemotherapy or the regularity of surveillance. However, nomograms have not become part of the treatment strategy.

A number of molecular markers such as MSI, 18q loss of heterozygosity, TP53, p21, among others, have been associated with prognosis in CRC patients. But none of these are routinely incorporated into clinical practice. Somatic RAS mutations have been associated with lack of response to anti-EGFR targeted therapies, and clinical guidelines worldwide now recommend testing for both KRAS and NRAS mutations if anti-EGFR therapy is contemplated in patients with stage IV disease.⁵⁴ In addition, when a KRAS or NRAS mutation is not found, some recommend V600E BRAF testing because the data suggest that those tumors are also unresponsive to anti-EGFR therapy. However, these mutations have not been incorporated into the staging system.

Based on recent advances in the molecular characterization of CRC, a number of multigene molecular signatures have been designed as prognosticators of recurrence and outcomes. The *Oncotype DX* Colon Cancer Assay, developed by Genomic Health, Inc. (Redwood City, CA, USA) is an assay based on the expression of 12 genes that play roles in cell-cycle and stromal responses.^{55,56} The assay was designed and validated using formalin-fixed, paraffin-embedded tissue samples from patients enrolled in the Cancer and Leukemia Group B (CALGB) 9581 cohort.^{57,58} The predictive model provides a score predicting 3-year recurrence risk in stage II colon cancers, and appears most effective in MMR-proficient T3 tumors. Another commercially available tool is ColoPrint, developed by Agendia (Amsterdam, The Netherlands). With a similar premise, this tool is an 18-gene signature found to be predictive of distant metastasis in stage II colon cancers.^{59,60} ColDx, developed by Almac (Craigavon, UK) is a microarray-based tool that uses 634 probes to identify patients with stage II colon cancer at high risk of recurrence.⁶¹ While these molecular signatures seem to determine risk of recurrence independent of other well-established risk factors, they have not been fully incorporated into clinical practice.

Table 68-4 Clinical and Pathologic Staging⁴

Definitions					
Primary Tumor (T)					
TX	Primary tumor cannot be assessed				
T0	No evidence of primary tumor				
Tis	Carcinoma in situ: intraepithelial or invasion of lamina propria ¹				
T1	Tumor invades submucosa				
T2	Tumor invades muscularis propria				
T3	Tumor invades through muscularis propria into pericorectal tissues				
T4a	Tumor penetrates to the surface of the visceral peritoneum ²				
T4b	Tumor directly invades or is adherent to other structures ^{2,3}				
Regional Lymph Nodes (N)					
Nx	Regional lymph nodes cannot be assessed				
N0	No regional lymph node metastases				
N1	Metastases in 1–3 regional lymph nodes				
N1a	Metastases in one regional lymph node				
N1b	Metastases in 2–3 regional lymph nodes				
N1c	Tumor deposit(s) in the subserosa, mesentery or nonperitonealized pericolic or perirectal tissues without regional lymph node metastasis				
N2	Metastases in 4 or more regional lymph nodes				
N2a	Metastases in 4–6 regional lymph nodes				
N2b	Metastases in 7 or more regional lymph nodes				
Distant Metastases (M)					
M0	No distant metastases				
M1	Distant metastases				
M1a	Metastasis confined to one organ or site (e.g., liver, lungs, ovary, and nonregional lymph node)				
M1b	Metastases in more than one organ/site or the peritoneum				
Anatomic Stage/Prognostic Factors					
Stage	T	N	M	DUKES ^a	MAC ^a
0	Tis	N0	M0	—	—
I	T1	N0	M0	A	A

Tumor regression grade (in tumors treated with neoadjuvant therapy)
KRAS mutation

SCREENING AND PREVENTION

The slow development of CRC from a benign polyp to an invasive cancer provides a window of opportunity for the detection and removal of premalignant adenomatous polyps and early-stage cancers. Removal of adenomatous polyps reduces the incidence of cancer, and the diagnosis of CRC at earlier stages reduces mortality.^{62,63} A number of prospective studies have proven that screening for colorectal polyps and cancer using a variety of methods reduces CRC mortality, and the reduction in mortality persists long-term after screening.^{64–66} There is good evidence that screening has contributed significantly to the drop in CRC mortality rates from a peak a few decades ago. Screening for CRC is cost-effective, in terms of the quality-adjusted life-years gained, compared to nonscreening. In the United States, screening for CRC is recommended for men and women over age 50, but compliance remains suboptimal because more than one-third of Americans report not having participated in a screening program.

Figure 68-6. Nomogram to predict 5-year and 10-year recurrence-free survival in colon cancer. Used by drawing a straight line up to the Points axis to determine how many points toward recurrence the patient should receive. Sum of the points received from each prognostic variable is then located along the total points axis. Then drawing a line down from the total Points axis to the 5-year or 10-year freedom from recurrence axes provides the patient's specific risk. RS, rectosigmoid colon; L, left colon; R, right colon; Sig, sigmoid colon; TC, transverse colon. (From Weiser et al. 2008, *J Clin Oncol* 26:380–385.)

Table 68-6 Tools for Colorectal Cancer Screening

a. Fecal tests. Detect primarily cancer
Guaiac-based fecal occult blood test (gFOBT)
Fecal immunochemical test (FIT)
Stool DNA test (sDNA)
b. Structural examinations. Detect polyps and colorectal cancer
Flexible sigmoidoscopy (FSIG)
Optical-colonoscopy (OC)
Double-contrast barium enema (DCBE)
Computed tomography colonoscopy (CTC)

Screening Tests

Numerous screening methods for CRC have been used over the years (Tables 68-6 and 68-7). These fall into one of two categories: stool tests, which detect the presence of blood or altered DNA in the stool; and structural tests, which identify polyps and cancers. Efficacy in detecting CRC, cost-effectiveness as a screening tool, supporting evidence, and patient acceptability vary for each of these tests.^{67–69}

Stool Tests

CRCs and polyps bleed more than the normal mucosa, and detecting occult blood in the stool is the basis of the most widely used screening tests. Blood is detected by searching the stool for hemoglobin using chemical or immunologic methods; patients found to have blood in the stool should then undergo colonoscopy. The original fecal occult blood tests (FOBTs) relied on guaiac-based detection of the pseudoperoxidase activity of hemoglobin. However, as pseudoperoxidase activity is not specific to human hemoglobin, foods such as red meat can produce false positives. Medications such as aspirin and nonsteroidal anti-inflammatory drugs can also cause a false-positive reaction. Other foods, in particular those rich in vitamin C, can cause false-negative results and should also be avoided before a test. Thus, for improved accuracy, a special diet and avoidance of these drugs should be followed for 2 to 3 days before FOBT. As most tumors bleed slowly and intermittently, the sensitivity of this test remains low. Rehydration of the test cards increases sensitivity, at the cost of reducing specificity. The sensitivity of the test increases with the number of samples tested; testing two samples per stool on three consecutive bowel movements is recommended. Several prospective, randomized trials have demonstrated that screening by FOBT, followed by total colonic evaluation with colonoscopy in individuals with a positive test, reduces mortality from CRC.^{70–72}

Fecal immunochemical tests (FITs) rely on antibodies that are specific to human hemoglobin, and the analysis of samples by automated quantification methods. FITs are as sensitive as the guaiac-based tests, but more specific in detecting human hemoglobin in stool. They therefore avoid the false-negative results in the presence of vitamin C, and the false positives obtained in guaiac-based testing from red meats. The test does not require dietary modification beforehand, and the handling of the specimens is less demanding. As with any fecal test, a positive result with FIT requires a complete colonoscopic examination. Several studies have demonstrated that FIT has better screening performance, compared to FOBT.^{73,74} As an additional consideration, FIT may be more easily implemented as a screening regimen, compared with sole usage of colonoscopy.⁷⁵ Based on this evidence, a number of countries have introduced screening programs utilizing these tools.

Detection of altered DNA from exfoliated tumor cells has been investigated as a screening test for CRC for years. Similar to the detection of hemoglobin, detection of altered DNA triggers patient referral for colonoscopy. Large, prospective studies of this test show fair sensitivity in detecting CRC and low sensitivity in detecting large adenomas, compared with colonoscopy.^{76,77} A more recent study using new stabilizing buffers, more discriminating markers, and more sensitive analytical methods, has shown that stool DNA testing is more sensitive than FIT in detecting CRC and advanced precancerous lesions. However, the specificity of stool DNA testing was found to be inferior to FIT, with roughly 10% of the screened individuals having a false-positive result.⁷⁸ There are concerns that a positive stool DNA test and negative colonoscopy may lead to additional and unnecessary work-up for malignancy. Therefore, screening guidelines of the U.S. Preventive Services Task Force do not currently recommend the fecal DNA test as a screening option.

Structural Tests

Two-thirds of CRCs and polyps are located in the sigmoid colon and rectum, and can be reached with a 60-cm flexible sigmoidoscope. The presence of adenomatous polyps in the rectosigmoid colon increases

the probability of finding additional polyps or cancers in more proximal segments of the large bowel. If an adenomatous polyp is found during flexible sigmoidoscopy, the patient should undergo a complete colonoscopy. Flexible sigmoidoscopy is safe, fast, requires minimal preparation, and can be performed in an office-based setting, as conscious sedation is not needed. The risk of perforation with flexible sigmoidoscopy is approximately 1 in 20,000, but the lack of sedation can occasionally be associated with discomfort, deterring some patients from undergoing future examinations. The effectiveness of flexible sigmoidoscopy as a screening modality requires examination to at least 40 cm from the anal verge, and the ability of the endoscopist to biopsy-suspected adenomas. The main limitation of flexible sigmoidoscopy is that it does not examine the entire colon. However, as distal tubular adenomas are often indicative of proximal advanced neoplasia, the efficacy of flexible sigmoidoscopy is greatest when patients with distal adenomas are subsequently referred for colonoscopy. Due to differences in the distribution of colorectal neoplasia in patients of different age, gender, and racial groups, the efficacy of flexible sigmoidoscopy may vary. Several case-control studies have demonstrated that screening by sigmoidoscopy reduces mortality from CRC by two-thirds in the setting of tumors located within reach of the sigmoidoscope.^{79,80} More recently, several prospective studies have demonstrated that screening with flexible sigmoidoscopy reduced CRC incidence and mortality by approximately 25%.^{81–83} The reduction in incidence occurs in both the proximal and distal colon, while the reduction in mortality applies mainly to tumors in the distal colon. The optimal interval between tests is still controversial. In some studies, flexible sigmoidoscopy was performed every 3 to 5 years. At least two prospective trials demonstrated a reduction in CRC incidence and mortality with only one flexible sigmoidoscopy screening between 55 and 64 years of age.^{83,84}

Although the evidence for combining FOBT and flexible sigmoidoscopy is weak, some studies have shown that the combination of these two screening methods is more effective in detecting colorectal neoplasia than each method used individually.⁸⁵ The combined approach has a theoretical advantage of detecting lesions located throughout the colon, but its impact on mortality from CRC is unknown. In the United States, annual FOBT combined with flexible sigmoidoscopy every 5 years is a common screening method for the average-risk population.

Colonoscopy is considered the most accurate test for the early diagnosis and prevention of CRC. It allows direct visualization of the mucosa of the entire colon and rectum, simultaneously allowing the biopsy or removal of suspicious lesions. Colonoscopy is also used to evaluate patients who have tested positive on other screening tests. However, colonoscopy is inconvenient, requires dietary modification and bowel preparation beforehand, is usually performed under conscious sedation, and carries a risk of complications of 1–2 per 1,000. Colonoscopy is also more expensive compared to other screening methods. Overall, patient acceptability of colonoscopy seems to be higher compared to other invasive screening methods, and it is now the most commonly used screening method in the United States. There is indirect evidence from microsimulation and case-control studies that colonoscopy reduces mortality.⁸⁶ However, randomized controlled trials proving that screening with colonoscopy reduces CRC mortality are lacking. Comparative studies show that colonoscopy is more effective in detecting advanced colonic neoplasia, in both men and women, than a single FOBT combined with sigmoidoscopy. Colonoscopy is more likely to detect preneoplastic polyps, but just as likely to detect invasive CRC as FITs. In addition, colonoscopy provides the protective benefit of screening the proximal colon.⁸⁷ For average-risk individuals colonoscopy screening should start at 50 years of age and be repeated every 10 years.

Table 68-7 Screening and Surveillance for Colorectal Cancer According to Risk⁷

Risk Category	Age to Begin	Recommendation	Comment
Average Risk			
	50	Annual FOB test plus flexible sigmoidoscopy every 5 years Colonoscopy every 10 years Double-contrast barium enema every 5 years CT colonography every 5 years	If positive, colonoscopy is indicated. Screening is recommended up to 75 years of age
Increased Risk – Patients with History of Polyps at Prior Colonoscopy			
Patients with small rectal hyperplastic polyps	—	Colonoscopy or other screening options at intervals recommended for average-risk individuals	An exception is patients with a hyperplastic polyposis syndrome. They are at increased risk for adenomas and colorectal cancer and need to be identified for more intensive follow-up
Patients with 1 or 2 small tubular adenomas with low grade dysplasia	5–10 years after the initial polypectomy	Colonoscopy	The precise timing within this interval should be based on other clinical factors (such as prior colonoscopy findings, family history, and the preferences of the patient and judgment of the physician)
Patients with 3–10 adenomas, 1 adenoma ≥1 cm, or any adenoma with villous features or high-grade dysplasia	3 years after the initial polypectomy	Colonoscopy	Adenomas must have been completely removed. If the follow-up colonoscopy is normal or shows only 1 or 2 small tubular adenomas with low-grade dysplasia, then the interval for the subsequent examination should be 5 years
Patients with ≥10 adenomas on a single examination	3 years after the initial polypectomy	Colonoscopy	Consider the possibility of an underlying familial syndrome
Patients with sessile adenomas that are removed piecemeal	2–6 months to verify complete removal	Colonoscopy	Once complete removal has been established, subsequent surveillance needs to be individualized based on the endoscopist's judgment. Completeness of removal should be based on both endoscopic and pathologic assessments
Increased Risk – Patients with Colorectal Cancer			
Patients with colon and rectal cancer should undergo high-quality perioperative clearing	3–6 months after cancer resection, if no unresectable metastases are found during surgery; alternatively, colonoscopy can be performed intraoperatively	Colonoscopy	In the case of nonobstructing tumors, this can be done by preoperative colonoscopy. In the case of obstructing colon cancers, CTC with intravenous contrast or DCBE can be used to detect neoplasms in the proximal colon
Patients undergoing curative resection for colon or rectal cancer	1 year after the resection (or 1 year following the performance of the colonoscopy that was performed to clear the colon of synchronous disease)	Colonoscopy	This colonoscopy at 1 year is in addition to the perioperative colonoscopy for synchronous tumors. If the examination performed at 1 year is normal, then the interval before the next subsequent examination should be 3 years. If that colonoscopy is normal, then the interval before the next subsequent examination should be 5 years. Following the examination at 1 year, the intervals before subsequent examinations may be shortened if there is evidence of HNPCC or if adenoma findings warrant earlier colonoscopy. Periodic examination of the rectum for the purpose of identifying local recurrence, usually performed at 3-to 6-month intervals for the first 2 or 3 years, may be considered after low anterior resection of rectal cancer

Increased Risk – Patients with a Family History			
Either colorectal cancer or adenomatous polyps in a first-degree relative before age 60 years or in 2 or more first-degree relatives at any age	Age 40 years, or 10 years before the youngest case in the immediate family	Colonoscopy	Every 5 years
Either colorectal cancer or adenomatous polyps in a first-degree relative age 60 or older or in 2 second-degree relatives with colorectal cancer	Age 40 years. Screening options at intervals recommended for average-risk individuals	Screening options at intervals recommended for average-risk individuals	Screening should be at an earlier age, but individuals may choose to be screened with any recommended form of testing
High Risk			
Genetic diagnosis of FAP or suspected FAP without genetic testing evidence	Age 10–12 years	Annual FSIG to determine if the individual is expressing the genetic abnormality and counseling to consider genetic testing	If the genetic test is positive, colectomy should be considered
Genetic or clinical diagnosis of HNPCC or individuals at increased risk of HNPCC	Age 20–25 years, or 10 years before the youngest case in the immediate family	Colonoscopy every 1–2 years and counseling to consider genetic testing	Genetic testing for HNPCC should be offered to first-degree relatives of persons with a known inherited MMR gene mutation. It should also be offered when the family mutation is not already known, but 1 of the first 3 of the modified Bethesda criteria is present
Inflammatory bowel disease, chronic ulcerative colitis, and Crohn colitis	Cancer risk begins to be significant 8 years after the onset of pancolitis or 12–15 years after the onset of left-sided colitis	Colonoscopy with biopsies for dysplasia	Every 1–2 years; these patients are best referred to a center with experience in the surveillance and management of inflammatory bowel disease

CRC, colorectal cancer; CSPY, colonoscopy; CTC, computed tomographic colonography; DCBE, double-contrast barium enema; FAP, familial adenomatous polyposis; FSIG, flexible sigmoidoscopy; HNPCC, hereditary nonpolyposis colon cancer; MMR, mismatch repair.

Double-contrast barium enema can detect most of the clinically important lesions in the colon but, as with colonoscopy, its effectiveness as a screening test for CRC is based only on indirect evidence. Similar to colonoscopy, it requires dietary modification and mechanical bowel preparation, and is associated with patient discomfort. In addition, a positive test mandates a colonoscopy. While double-contrast barium enema every 5 years should provide the same degree of protection as the other screening strategies, it is rarely used as a primary screening method today. Its clinical role as a screening tool at this time is primarily for visualization of the colon in patients who cannot undergo a complete colonoscopy.

Computed tomography colonography (CTC), also referred to as virtual colonoscopy, involves thin-section, multidetector, helical CT, and three-dimensional viewing for interpretation.⁸⁸ CTC identifies 90% of cancers or adenomas measuring more than 10 mm in diameter in asymptomatic individuals 50 years of age or older.⁸⁹ It is more sensitive than other screening methods, but can miss flat lesions and polyps smaller than 10 mm in diameter. CTC obviates some of the drawbacks of colonoscopy, such as the need for sedation and recovery time, but also has downstream consequences: it delivers a dose of radiation that may become substantial with repeated examinations, and detects incidental extra-colonic findings that may trigger expensive, and sometimes unnecessary diagnostic investigations. Furthermore, it requires standard bowel preparation and gaseous distension of the colon. New methods of tagging and subtracting residual stool may obviate the routine need for mechanical bowel preparation. Finally, patients with lesions found on CTC still require full visualization of the colon by colonoscopy. CTC is now considered an acceptable screening alternative for average-risk individuals, starting at 50 years of age; the interval between such examinations remains uncertain, although a 5-year interval has been suggested, based on computer simulation models.⁹⁰

Risk Categories

Patients with symptoms of CRC should undergo the appropriate diagnostic studies; they are not candidates for screening. Screening recommendations for the general population are based on individual risk assessment. Based on the past medical history and family history of CRC or polyps, individuals are assigned to one of three risk categories, with different screening recommendations (Table 68-7).⁹¹

Average Risk

People at average risk for the development of CRC (asymptomatic men and women without risk factors, over 50 years of age in the United States and 60 in the United Kingdom) could undergo yearly FOBT, combined with flexible sigmoidoscopy every 5 years. People with a positive FOBT or a polyp identified by flexible sigmoidoscopy should undergo entire colon and rectum examination by colonoscopy. Double-contrast barium enema every 5 years, or colonoscopy every 10 years, is an accepted screening alternative in the average-risk population. CTC every 5 years is also an option. Digital rectal examination (DRE) should be performed at the time of sigmoidoscopy or colonoscopy in all individuals.

Increased Risk

Family History. Individuals with a first-degree relative (parent, sibling, or child) with CRC or adenomatous polyps diagnosed before 60 years of age should start screening with colonoscopy at 40 years of age or 10 years younger than the earliest diagnosis in their family, whichever comes first. The test should be repeated every 5 years. Individuals with one first-degree relative with CRC or adenomatous polyp diagnosed at 60 years of age or older, or with two or more second-degree relatives (grandparent, grandchild, aunt, uncle, niece, nephew, half-sibling) with CRC or adenomatous polyps at any age, should undergo screening as average-risk individuals – but starting at 40 years of age. Patients with one second-degree relative or one or more third-degree relatives (first cousin) affected are considered to be at average risk.

History of Polyps at Previous Colonoscopy. Patients undergoing endoscopic excision of a small (<1 cm) adenomatous polyp should have the entire colon examined at the time of the polypectomy. Colonoscopy should be repeated 5 years later. If the test is negative, they should then follow the screening recommendations for average risk.⁹²

Patients with more than three adenomas, adenomas with villous features or high-grade dysplasia, or a large adenomatous polyp (>1 cm) who have the entire colon examined at the time of polypectomy, should undergo complete colonoscopy 3 years later – and, if normal, every 5 years thereafter.

A complete colonic examination should be carried out before surgery in any patient undergoing a planned curative resection for CRC. The colonoscopy should be repeated at 1 year to exclude metachronous lesions. If the examination at 1 year is normal, it should be repeated after 3 years, and every 5 years thereafter if the previous one was normal.

Patients with Colorectal Cancer. Patients with colon and rectal cancer should undergo high-quality perioperative clearing of polyps with colonoscopy 3 to 6 months after resection, if not performed before surgery. Surveillance after curative resection is described in detail in Surveillance after Curative Resection for Colon and Rectal Cancer section.

High Risk

This category includes individuals from families diagnosed with hereditary forms of CRC.

Familial Adenomatous Polyposis. Once the diagnosis of FAP is established, the patient should undergo colectomy, or a yearly colonoscopy until colectomy. Upper gastrointestinal endoscopy should be performed every 1 to 2 years. Siblings and children of a patient with FAP should start surveillance by flexible sigmoidoscopy at puberty.

MYH-Associated Polyposis. Depending on the individual, age of presentation, and number and size of polyps, the patient may be advised to undergo a prophylactic colectomy or yearly colonoscopy beginning at 25 years of age. Upper gastrointestinal surveillance should be performed following the guidelines for patients with FAP.

Lynch Syndrome. Individuals from families fitting the Amsterdam criteria for HNPCC should have a colonoscopy at 21 years of age, then every 2 years until 40 years of age, and yearly thereafter. Genetic counseling and testing should be considered.

At-risk members of families with hereditary cancer syndromes should be informed about the benefits and limitations of genetic counseling and genetic testing.

Consequences of Screening

The full spectrum of clinical consequences of screening, other than the prevention of deaths from CRC, is difficult to predict because every screening strategy initiates a cascade of events, each one with

uncertain probability. The rate of false-positive tests, the number of colonoscopies performed, the complications of the screening and diagnostic tests, and the number of patients who may require surveillance as a consequence of screening, are complex factors that arise at different times over several decades. However, cost-effectiveness analysis in the United States has demonstrated that screening for CRC in average-risk patients, according to the strategies outlined above, compares favorably with other healthcare interventions such as mammography or treatment of mild hypertension.^{93,94} It is important to understand that screening does not completely eliminate the risk of CRC. Up to 9% of CRCs are diagnosed within 6 to 36 months after a screening colonoscopy.^{95,96} These interval cancers tend to be preferentially located in the proximal colon. This may be related to failure to reach the proximal colon, residual stool obscuring the view in the proximal colon, or different characteristics of the proximal lesions that makes them more difficult to detect or remove.

Implementation of Guidelines

The general population has limited awareness of the risks of CRC or its symptoms; as a result the number of individuals participating in screening programs has been low. The dissemination of information to patients is an essential part of the screening program. Primary care physicians have a responsibility to inform their patients about their risk of CRC, the benefits of screening and different screening strategies, and to set up a system for implementing these guidelines.^{94,97,98} Through such efforts, the proportion of adults 50 to 75 years of age having colonoscopy has increased steadily in the last decade: from 19.1% in 2000 to 55% in 2010.³

DIAGNOSIS

While the proportion of CRCs diagnosed through screening is increasing, most are still diagnosed after patients become symptomatic. CRC can cause a myriad of symptoms, many of which are nonspecific and highly prevalent among healthy individuals. Therefore, the diagnosis of colorectal carcinoma often requires a high index of suspicion.

Symptoms and Signs

The most common symptoms in patients with CRC are abdominal pain, change in bowel habits, rectal bleeding, anemia, anorexia, and weight loss. The clinical manifestations of CRC differ depending on the location and stage of the tumor.

Abdominal pain is nonspecific; it may be localized to any quadrant of the abdomen, or may be diffuse. When the pain is persistent and colicky, it is more likely to represent obstructive symptoms resulting from a left-sided lesion. More localized tenderness with signs of localized peritonitis indicates local invasion of the adjacent peritoneum or perforation. It can be difficult to distinguish the pain associated with diverticular disease from that due to a carcinoma in the sigmoid or descending colon. Patients with diverticular disease may also have an underlying carcinoma. Abdominal pain may occasionally be related to extensive metastatic disease in the liver or retroperitoneal lymph nodes. Rectal cancer can also cause perineal discomfort and is often associated with tenesmus, the sensation of incomplete defecation. A locally advanced rectal cancer can also cause sacral or sciatic pain.

An unexplained change in bowel habits lasting more than 2 weeks requires investigation for CRC. Constipation associated with colicky abdominal pain is a common manifestation of partially obstructing tumors. Abdominal pain, constipation, and abdominal distension suggest a complete colonic obstruction, which is more common in tumors located in the sigmoid colon and rectum. Some patients with sigmoid or rectal cancer may also complain of diarrhea, which may sometimes be bloody.

Bleeding from tumors in the sigmoid colon and rectum is often wrongly attributed to hemorrhoids or other benign anal conditions. However, blood from hemorrhoids is usually bright red and is accompanied by anal discomfort; the bleeding is intermittent and splashes the toilet pan. Anal fissure is also a common cause of rectal bleeding; the blood is often bright, occurring after defecation, and is typically associated with sharp anal pain triggered by defecation. Painless defecation with rectal blood that is darker in color and mixed in with stool is more likely to be secondary to an underlying carcinoma. Rectal bleeding, particularly when associated with tenesmus, requires a thorough diagnostic investigation to exclude an underlying rectal tumor.

The development of nonspecific anemia of unknown origin is a common manifestation in patients with a carcinoma in the proximal colon. Patients with unexplained microcytic anemia should be

examined initially with colonoscopy. Anorexia and weight loss frequently accompany CRC, and are often associated with advanced disease. The differential diagnosis in these patients is a gastric carcinoma, but when investigations are negative it is important to exclude a large-bowel malignancy. As the bowel lumen is larger and the stools overall looser in the proximal colon, obstructive symptoms are uncommon; therefore, patients with tumors proximal to the splenic flexure often present with advanced disease.

It should be remembered that the presence of colon cancer can also be identified incidentally during investigations for other pathologies such as gallstones, gynecologic, or urinary conditions. A complete family history, with emphasis on past history of CRC or polyps, is essential to diagnose some hereditary cancer syndromes. A family history of endometrial, gastric, urologic, or other HNPCC-associated cancers is also important because it may help in diagnosing Lynch II syndrome.

The evaluation of patients suspected of CRC requires a complete physical examination. Features that should arouse suspicion of malignancy include pallor, palpable abdominal mass, and a palpable mass on DRE. Hepatomegaly indicates advanced disease with extensive liver metastases, and consequently a very poor prognosis. A hard mass in the pouch of Douglas felt on DRE may indicate peritoneal carcinomatosis. Other signs of an underlying CRC include pneumaturia, ischiorectal or perineal abscesses, or even deep venous thrombosis.

The differential diagnosis of CRC includes diverticulitis, irritable bowel syndrome, inflammatory bowel disease, ischemic colitis, and benign anorectal conditions such as hemorrhoids or rectal mucosal prolapse.

Diagnostic Evaluation

Patients with symptoms suggesting CRC should have a colonoscopy to evaluate the entire colon (Fig. 68-7). The examination should be complete, as up to 4% of patients with CRC have synchronous cancers and many more have colorectal polyps.^{99,100} Up to one-third of these synchronous cancers are in locations requiring a different surgical resection, further emphasizing the importance of complete colonoscopy. As many patients undergo minimally invasive surgery today, the endoscopist should mark the vicinity of the tumor with India ink to help locate the lesion intraoperatively. CT colonography and DCBE are less effective in investigating patients with symptoms suggestive of CRC, but they are useful in patients with partially obstructive tumors, in whom colonoscopy cannot be completed. In patients with obstructive lesions, the proximal colon can be examined either by preoperative imaging studies such as PET-CT, or intraoperatively by direct palpation of the colon. In any case, patients with a complete colonoscopy before surgery should have a surveillance colonoscopy 6 months after surgery.

Assessment of the extent of disease at the time of diagnosis is important because clinical stage, particularly in rectal cancer, dictates treatment decisions. A CT scan of the chest, abdomen, and pelvis with intravenous and oral contrast is important in order to locate the tumor, detect mesenteric nodes, and exclude liver metastasis and gross peritoneal carcinomatosis (Fig. 68-7). In addition, preoperative imaging helps the surgeon plan the resection. In patients with iodine allergy, and in patients with undetermined lesions on CT, a PET-CT or and abdominal or pelvic MRI may provide additional information.

Laboratory evaluation includes complete blood cell count, coagulation parameters, and chemistry panel. Preoperative CEA should be measured because it provides prognostic information, and can be useful during patient surveillance.

TREATMENT

Surgery is the primary treatment for CRC, but for many patients surgery is not the initial form of treatment and some do not require surgery at all. Treatment is different for colon than for rectal cancer, and depends also on the clinical stage of the tumor. Treatment decisions must also take into account the patient's performance status, comorbidities, hereditary CRC predisposition, as well as desires and expectations.

Preoperative Preparation

All patients undergoing surgery for colon and rectal cancer require similar preoperative preparation aimed at optimizing the technical success of the procedure and avoiding perioperative complications. Surgical site infection (SSI) is the most common complication after colon and rectal cancer resection,

occurring in 4% to 26% of cases.^{101,102} In addition to causing patient suffering, SSIs lengthen hospital stay and increase costs.¹⁰³ The institutional rate of SSI after colorectal surgery is now an important quality metric for several benchmarking programs. A number of federal and state-wide initiatives aimed at improving surgical care recommend implementing measures to reduce the rate of SSI and other complications in patients undergoing elective colorectal surgery.^{104,105}

Figure 68-7. Staging modalities for colorectal cancer. **A:** Obstructing colon cancer at colonoscopy. **B:** Polypoid colonic tumor at colonoscopy. **C:** Cecal circumferential tumor with regional lymphadenopathies. **D:** Liver metastases of colorectal origin.

The colon has the largest concentration of bacteria in the human body. A gram of feces contains 10¹¹ polymicrobial bacteria, mostly gram negatives and anaerobes.¹⁰⁶ Oral mechanical bowel preparation using polyethylene glycol to reduce the bacterial load and risk of intraoperative fecal spillage has been considered an axiom in colon and rectal surgery. However a number of prospective trials have failed to demonstrate benefit from mechanical bowel cleansing in preventing SSIs.^{107,108} These results were confirmed by a Cochrane systematic review of 5,805 patients; the authors concluded that there is no statistically significant evidence that patients benefit from mechanical bowel preparation or the use of rectal enemas.¹⁰⁹ Another recent systematic review by the Agency for Health Care Research and Quality reached similar conclusions. Oral mechanical bowel preparation appeared to be protective, compared to no preparation, for peritonitis or intra-abdominal abscess, but the evidence was weak. The study could not draw any conclusion on potential harms, such as dehydration and electrolyte imbalances, related to use of oral mechanical bowel preparation.¹¹⁰ Despite the lack of solid data, many surgeons still recommend oral mechanical bowel preparation because manipulation and suturing is easier with a clean colon.

High-quality evidence indicates that antibiotics covering aerobic and anaerobic bacteria, delivered orally or intravenously (or both) prior to elective colorectal surgery, reduce the risk of postoperative surgical wound infection by as much as 66%.¹¹¹ Oral antibiotics, neomycin- and erythromycin-based, are delivered the day before surgery, in combination with the oral mechanical bowel preparation. For patients without penicillin allergy, a second-generation cephalosporin (cefotetan or cefoxitin) is administered intravenously within 30 minutes of the surgical incision, with re-dosing during the procedure as required according to the half-life of the drug and the duration of surgery. For penicillin-allergic patients, metronidazole or clindamycin combined with either ciprofloxacin or gentamicin is

acceptable, as are aztreonam and fluoroquinolones.¹¹² Ertapenem, a long-acting carbapenem active against gram negatives and anaerobes, is an accepted alternative to second-generation cephalosporins for prophylaxis in CRC. Ertapenem has a long life and does not require re-dosing in prolonged procedures, but has been associated with increasing risk of *Clostridium difficile* infection.¹¹³ Other measures that prevent SSI include tight glucose control in diabetic patients, smoking cessation, clipping rather than shaving the skin of the abdominal wall, and maintaining normothermia and adequate oxygenation during anesthesia.¹¹⁴

Patients undergoing surgery for CRC are also at risk of deep venous thrombosis and pulmonary embolism, and should have thromboembolic prophylaxis with unfractionated heparin or low-molecular-weight heparin during the peri- and postoperative periods.¹¹⁵

As the incidence of CRC increases with age, many patients have cardiovascular or respiratory conditions requiring medical clearance before surgery. While technical advances have made CRC operations safer, optimal outcomes require special effort to ensure that the patient's overall health is optimal at the time of surgery. Many CRC patients have other comorbid conditions such as diabetes, hypertension, and coronary artery disease requiring medical evaluation before undergoing surgery. Comorbidities can impact decision-making and affect short- and long-term outcomes. Patient clinical and performance status should be optimized to reduce the risk of perioperative complications. Fertility options should be discussed with all individuals of child-bearing potential.

Patients who may require a stoma should be seen before surgery by an enterostomal therapist. Adequate marking of the site improves outcomes for patients requiring a stoma. Preoperative teaching shortens the time patients require to become proficient managing the stoma, and reduces hospital stay.¹¹⁶

The Enhanced Recovery After Surgery (ERAS) protocols were introduced in open colorectal surgery in the 1990s, with the aim of speeding patient recovery, improving patient outcomes and satisfaction, shortening hospitalization, and reducing healthcare costs.¹¹⁷ ERAS protocols span the entire perioperative period, and attempt to minimize surgical stress and postoperative ileus through patient education, preoperative hydration and carbohydrate loading, goal-directed intraoperative fluid management, narcotic sparing for intraoperative and postoperative pain control, and early mobilization and oral feeding in the postoperative period. A number of prospective trials have indicated that the implementation of ERAS protocols reduces length of hospital stay, compared to conventional recovery in patients undergoing open or minimally invasive surgery for CRC.^{118,119} A recent systematic review and a meta-analysis confirmed that ERAS protocols resulted in a shorter length of stay and a reduction in overall complications, with no difference in mortality and surgical complications.^{120,121} Similar results have recently been reported from an international registry.¹²²

Principles of Surgical Treatment

The goal for any curative-intent surgery is to remove the tumor-bearing segment of the bowel with adequate margins, along with en bloc excision of the mesentery containing the feeding vessels and regional lymph nodes. The location of the primary tumor determines lymphatic drainage and dictates the extent of the resection. Lymphatic capillaries are primarily located in the submucosal and subserosal layers of the bowel wall. The lymphatic flow in the colon is primarily circumferential, with longitudinal spread along the bowel wall thought to be less than 1 cm in each direction. Therefore, a 5-cm margin of normal bowel on either side of the primary tumor is considered sufficient to avoid anastomotic recurrence. The length of the terminal ileum resected in patients with rectal cancer does not influence the risk of anastomotic recurrence. In the rectum, where the longitudinal lymphatic flow is primarily upward, cancer cells rarely spread distally along the bowel wall farther than 1 cm from the macroscopic distal end of the tumor. Consequently, a 2-cm margin of normal bowel distal to the tumor, or even less in patients treated with neoadjuvant therapy, is considered appropriate to an oncologically safe resection.¹²³

The lymphatic channels in the bowel wall drain to the regional nodes, which are classified in different groups according to their proximity to the bowel and its blood supply (Fig. 68-8). The “epicolic” nodes are located in the bowel wall under the peritoneum, usually close to the epiploic appendices. The “paracolic” lymph nodes are located along the marginal vessels. Next, the “intermediate” nodes are positioned in the middle of the mesentery. Finally, the “central” or “apical” lymph nodes are located close to the root of the mesentery, near the origin of the named vessels. While CRC generally spreads sequentially from the paracolic to the central or apical lymph nodes, nodal metastases skipping one of the groups are common.¹²⁴

The extent of the mesenteric resection is determined by the need to remove all the lymph nodes draining the corresponding segment of bowel, including the central lymph nodes located at the origin of the named feeding blood vessels. As most tumors are located between two named vascular pedicles, both of these should be resected at their origin. When suspected of being involved by tumor, the central nodes should be marked on the specimen, as they have negative prognostic information. Other lymph nodes located away from the feeding vessels and suspected of tumor involvement during surgery, should be removed and analyzed, because in some patients the lymphatic drainage does not follow an orderly pattern.^{125,126} If residual metastatic lymph nodes remain after sampling, the resection should be considered incomplete.

Figure 68-8. Anatomy of the colon. A: Epicolic lymph nodes. B: Paracolic lymph nodes. C: Intermediate lymph nodes. D: Apical-central lymph nodes.

While achieving safe oncologic margins and adequate lymphadenectomy are the main considerations when performing a surgical resection for CRC, ensuring an adequate blood supply to the bowel ends, and maintaining tension-free anastomosis, are also important in order to avoid anastomotic complications.

Locally advanced tumors attached to other organs should be removed en bloc with contiguously involved structures. As it is impossible to distinguish clinically or radiographically between inflammatory adhesions and tumor infiltration, it is preferable to perform an en bloc resection of any organ attached to the primary tumor, rather than spilling cancer cells by separating structures infiltrated by tumor. Intraoperative tumor perforation has negative prognostic implications. It is important to report the completeness of the resection (R0, R1, or R2), combining clinical and pathologic information, to determine risk of locoregional recurrence and long-term prognosis.

The concept of the no-touch technique, with initial control of the vascular supply before manipulation of the tumor to avoid releasing cancer cells into the blood stream, has not been shown to be associated with improved outcomes.¹²⁷ However, early vascular control with medial-to-lateral dissection of the mesentery, before mobilization of the colon, is the preferred approach during minimally invasive colorectal surgery, because it helps identify all vascular and retroperitoneal structures.

Proper surgical technique is crucial in achieving optimal results in CRC patients. The removal of the rectum along with its mesorectal envelope, using sharp dissection along normal anatomical planes – an operation called total mesorectal excision, or TME – is associated with a reduced risk of local tumor

recurrence.^{128,129} Application of the same surgical principles to colon cancer, including the removal of all the lymph node-bearing mesentery to the origin of the named blood vessels – an operation called complete mesocolic excision or CME – is also associated with a lower rate of local tumor recurrence in colon cancer patients.¹³⁰ Differences in expertise and surgical technique probably explain surgeon and institutional differences in outcomes among patients treated for CRC. A recent study from Denmark has shown that CME surgery is associated with better disease-free survival than conventional cancer resection for patients with stage I to III colon adenocarcinoma.¹³¹

TREATMENT OF LOCALIZED COLON CANCER

Malignant Colonic Polyps

The identification of a focus of invasive carcinoma in a polyp removed by snare excision during colonoscopy represents a surgical dilemma. These types of polyps are often referred to as “malignant polyps,” to distinguish them from lesions that are almost exclusively invasive adenocarcinoma with exophytic or polypoid morphology. Malignant polyps are encountered more often because tumors are diagnosed at an earlier stage, as a result of screening programs. Although there are some lymphatic channels in the lamina propria, tumors superficial to the muscularis mucosa (also known as intramucosal carcinoma, carcinoma in situ, or Tis) are considered to carry no risk of lymph node metastasis. When the malignant cells penetrate beyond the muscularis mucosa they can access the lymphatic channels of the submucosa and metastasize to the regional lymph nodes. This risk of nodal metastasis depends on the morphology of the polyp, the depth of the invasive component, the presence of unfavorable histologic features (grade 3 or 4, angiolymphatic invasion, perineural invasion) and the margin of resection.¹³² Imaging studies are usually of no help in these patients, except to exclude distant metastases (which are uncommon). In pedunculated polyps with focus of invasive cancer located in the head, neck, or stalk of the polyp, with favorable histologic features, resected with negative margins, the risk of nodal metastasis is small (Fig. 68-9). In these circumstances additional surgery is considered unnecessary, as the risk of surgery may outweigh the risk of residual tumor in the bowel wall or nodal metastasis. On the other hand, patients with pedunculated polyps with focus of invasive adenocarcinoma reaching the base of the polyp, sessile polyps with focus of invasive adenocarcinoma, the presence of adenocarcinoma at the resection margin, and malignant polyps with unfavorable histologic features, are at risk of regional nodal metastasis, and should be offered surgical resection.^{133,134} Other factors such as the location of the polyp in the colon or rectum,¹³⁵ the patient’s comorbidities and performance status, and the patient’s desires, should be taken into consideration. Therefore, a final decision should only be made after full review of the pathology reports, and disclosure to the patient of the risks and benefits of each approach.

Figure 68-9. Malignant polyp. Haggitt levels of invasion. Level 0, Noninvasive, severe dysplasia; Level 1, Invading through muscularis mucosa but limited to the head of pedunculated polyp; Level 2, Invading the neck of pedunculated polyp; Level 3, Invading the stalk of pedunculated polyp; Level 4, Invading into submucosa of the bowel wall below the stalk of a pedunculated polyp. All sessile polyps.

Surgery for Localized Colon Cancer

Patients with biopsy-proven adenocarcinoma of the colon without evidence of distant metastasis, and

without contraindications to major surgery, should be treated with surgical resection. The extent of a colon cancer resection is dictated by the location of the primary tumor. Tumors in the cecum and ascending colon require a right hemicolectomy that implies division of the ileocolic, right colic, and sometimes the right branch of the middle colic vessels (Fig. 68-10). The portion of the omentum attached to the removed segment of colon should be resected en bloc with the colon and mesentery. Tumors located at the hepatic flexure and in the right side of the transverse colon require an extended right colectomy that, in addition to the ileocolic and right colic vessels, requires division of the middle colic vessels at their origin (Fig. 68-10). Tumors in the mid portion of the transverse colon can be treated with an extended right colectomy, or a transverse colectomy. A transverse colectomy involves division of the middle colic vessels only, but often requires mobilization of both the hepatic and splenic flexure to ensure a tension-free anastomosis (Fig. 68-10). Tumors located in the distal transverse colon, splenic flexure, and proximal descending colon can be treated with a left hemicolectomy, which requires division of the left branch of the middle colic and left colic artery at its branch point from the inferior mesenteric artery (Fig. 68-10). Locally advanced tumors located in the transverse colon can metastasize to the regional lymph nodes located along the greater omentum and gastroepiploic arcades, leading some surgeons to recommend removal of the omentum with the gastroepiploic arcade. In these patients, an omentectomy with division of the gastroepiploic vessels at their origin may be necessary for complete nodal control.¹³⁶ However, the benefit of such an extended lymphadenectomy is debated. Sigmoid tumors require sigmoid colectomy, which includes the superior rectal artery and its takeoff from the inferior mesenteric artery (Fig. 68-10).

Patients with synchronous tumors, which occur in up to 5.3% of patients with CRC, should be investigated for hereditary CRC syndromes or other predisposing conditions. Patients with sporadic synchronous cancers can be treated with separate resections, or an extended resection incorporating both lesions, depending on the location of the primaries.¹³⁷ When performing a segmental resection, it is important to preserve the blood supply to the intermediate segment of colon in order to avoid ischemia, which can lead to perioperative complications. Synchronous tumors in patients with HNPCC, or other risk factors such as inflammatory bowel disease, are indications for a subtotal or total colectomy.

Figure 68-10. Segmental colonic resections. **A:** Right colectomy. **B:** Extended right colectomy to transverse colon. **C:** Transverse colectomy. **D:** Right colectomy extended to splenic flexure. **E:** Left colectomy. **F:** Sigmoidectomy.

A number of well-conducted prospective trials have proved that laparoscopic colectomy for cancer is associated with short-term benefits and equivalent long-term oncologic outcomes, compared with the traditional open surgical approach ([Table 68-8](#)). Patients treated laparoscopically have less postoperative pain, earlier return of bowel function, shorter hospital stay, and a decreased rate of complications. However, laparoscopic surgery is technically challenging and has a long learning curve. Laparoscopy may be particularly difficult in patients with multiple adhesions from previous surgery, in obese patients, and in patients with locally advanced disease. Late conversion from laparoscopic to open surgery (also known as reactive conversion) is associated with higher complication rates compared to open surgery, while early or preemptive conversion is associated with complication rates similar to open surgery.¹³⁸

Laparoscopic colectomy is typically performed using a number of ports, usually 3 to 5, and a specimen extraction site. Additional expertise allows minimally invasive surgery to use fewer ports, smaller instruments, and shorter incisions. This trend has resulted in the single port laparoscopic surgery (SPLS) for the treatment of colon and rectal cancers. The operation is performed through a small port located at the specimen extraction site. The camera and the operating ports are all positioned through the SPLS device. A recent systematic review of 38 case series, including 565 patients operated by SPLS, suggested that the procedure is feasible but technically challenging. Evidence regarding its safety was limited.¹³⁹

Table 68-8 Open versus Laparoscopic Colon Resections, Results of the Most

Representative Series

Open/Laparoscopic	COST ^{8,9} (2004–2007)	COLOR (2005–2009) ^{10,11}	CLASICC ^{12–15} (2005–2007–2010–2013)	Leung ¹⁶ (2004)	ALCCAS ¹⁷ (2008)

The authors compared results of patients included in this review with those of a group of 3,526 patients treated with conventional laparoscopic colectomy and included in a Cochrane Review. They found that, in spite of lower BMI and smaller tumors, SPLS did not result in less postoperative pain or shorter hospital stay, compared to conventional laparoscopic surgery.¹³⁹

The introduction of robotic platforms, which enhance the visualization and dexterity of the surgeon, has added a new dimension to minimally invasive colon cancer surgery. The evidence accumulated so far indicates that robotic colon resection is associated with lower conversion rates, similar short-term outcomes, and higher costs, compared to conventional laparoscopic colon resection.¹⁴⁰

Postoperative Adjuvant Therapy for Localized Colon Cancer

Many patients with what appears to be localized colon cancer at the time of diagnosis develop recurrence after a curative-intent surgery. These recurrences are attributed to micrometastases that are already present, but clinically undetectable, at the time of diagnosis. Postoperative adjuvant chemotherapy aims to improve survival by eradicating micrometastatic disease. Numerous chemotherapeutic agents are now considered for adjuvant therapy, mostly based on their efficacy as observed in the setting of metastatic colon cancer. However, the mainstays of adjuvant therapy following resection of localized colon cancer remain fluoropyrimidines (5-fluorouracil [5-FU] and capecitabine) and oxaliplatin.

5-FU, a member of the family of antimetabolites, is a pyrimidine analog that works by irreversible inhibition of thymidylate synthase (TS), the rate-limiting enzyme in pyrimidine nucleotide synthesis, and by incorporation of its metabolites into RNA and DNA. 5-FU can only be delivered intravenously and is commonly administered with leucovorin, a reduced folate that is thought to stabilize fluorouracil's interaction with the enzyme TS. Capecitabine is an oral prodrug of fluorouracil that is absorbed intact through the gastrointestinal mucosa and undergoes enzymatic conversion to fluorouracil. Response rates to fluoropyrimidine, as first-line therapy alone for metastatic CRC, are only around 10% to 20%. Neutropenia, stomatitis and diarrhea are the most common side effects of 5-FU. The toxicity profile for capecitabine is similar to 5-FU, with hand-foot syndrome being more frequent. Oxaliplatin produces cytotoxic effects by forming both inter- and intra-strand cross links leading to disruption of DNA replication and apoptosis. As a single agent, oxaliplatin has limited effect in CRC; but in combination it enhances the cytotoxic effect of fluoropyrimidines, possibly through downregulation

of TS. The most relevant side effect of oxaliplatin is a progressive and often irreversible peripheral neuropathy. Other chemotherapy agents commonly used in patients with metastatic CRC have not shown proven benefit in the adjuvant setting.

The use of adjuvant therapy for stage III colon cancer was first shown to provide measurable benefit in the National Cancer Institute (NCI) Cooperative Intergroup trial INT-0035. Patients who received 5-FU and levamisole for 1 year after surgical resection had a 33% risk-reduction in death or recurrence, compared to those who underwent surgery alone.^{141,142} Since then, we have come to recognize that levamisole is overall an inactive agent; therapeutic combinations have evolved and have been tested rigorously.¹⁴³ A number of multi-institutional prospective, randomized trials have demonstrated a survival advantage with postoperative chemotherapy in selected patients after curative-intent surgery, compared to surgery alone. Pooled analyses of these trials have reported an approximately 30% reduction in recurrence, and 26% improvement in survival, in patients with stage III colon cancers treated with 6 months of postoperative fluoropyrimidine-based chemotherapy.^{144,145} More recently, the landmark MOSAIC (Multicenter International Study of oxaliplatin, fluorouracil, and leucovorin in the Adjuvant Treatment of Colon Cancer) trial, which randomized 2,246 stage II/III colon cancer patients to 5-FU/leucovorin with or without oxaliplatin, reported an additional 20% reduction in recurrence and 5% improvement in 5-year disease-free survival (73.3% vs. 67.4%; $p = 0.003$) in patients treated with 5-FU/leucovorin plus oxaliplatin, compared to 5-FU/leucovorin alone.^{146,147} Based on these results, the current recommendation for patients with stage III colon cancer following curative-intent surgery consists of 6 months of 5-FU/leucovorin and oxaliplatin (FOLFOX), or capecitabine and oxaliplatin (CAPEOX).

Several studies have proven that the addition of irinotecan – a topoisomerase I inhibitor that is effective in metastatic CRC – to standard fluoropyrimidines is not superior to fluorouracil/leucovorin combinations alone in stage III colon cancers.¹⁴⁸ Similarly, bevacizumab (anti-VEGF-A) and cetuximab (anti-EGFR), two biologic agents that have shown efficacy in metastatic disease, do not improve survival, compared to FOLFOX alone.^{149–151} Therefore, at the present time there is no role for irinotecan, bevacizumab, or cetuximab in the adjuvant treatment of CRC.

The use of adjuvant chemotherapy after curative resection for stage II CRC has been controversial for more than a decade. Three prospective, randomized trials have addressed the subject using 5-FU-based regimens,^{142,152,153} all of them failing to show a clear benefit of adjuvant treatment over observation alone. The addition of oxaliplatin to the adjuvant regimen does not seem to improve the results of pyrimidine-based regimens for stage II. Most of the evidence for adjuvant treatment in stage II CRC comes from pooled analyses, in which stage II and III CRC patients, undergoing different chemotherapy regimens and controls, are analyzed. The most influential one, including 37 trials and 11 meta-analyses, found a significant improvement in DFS for 5% to 10%, favoring adjuvant chemotherapy; nevertheless, no difference in OS was observed.¹⁵⁴ Therefore, postoperative adjuvant chemotherapy is still not routinely recommended after curative resection for stage II CRC. However, there is evidence that some node-negative patients at high risk for recurrence may benefit from postoperative adjuvant chemotherapy. Determining which patients are at high risk has most commonly included consideration of features such as tumor perforation, T4 category tumors, poorly differentiated histology, lymphovascular or perineural invasion, and patients with fewer than 12 nodes in the surgical specimen (who are considered inadequately staged).¹⁵⁵ At the present time, the use of adjuvant therapy for stage II disease ought to be weighed carefully by a multidisciplinary team, with adequate counseling of the patient. As mentioned earlier, some predictive nomograms may help stratify risk in patients with stage II disease, enabling us to more effectively select those more likely to benefit from adjuvant therapy; however, these tools have not been widely incorporated into clinical practice.

The search for molecular prognosticators aimed at stratifying stage II patients according to the risk of relapse, is an active area of research. MMR deficiency has been associated with an improved prognosis, but a decreased benefit from fluoropyrimidine-based adjuvant therapies, in patients with stage II disease.¹⁵⁶ Because of this, MMR testing is recommended for patients with stage II disease. Current guidelines recommend no use of single-agent fluoropyrimidine treatment for patients with stage II tumors exhibiting MSI or MMR deficiency. The multi-gene molecular signatures discussed previously were developed, in large part, to stratify risk in patients with stage II CRC, and to identify those most likely to benefit from adjuvant chemotherapy. While initial results are promising, there is insufficient evidence to recommend their use in selecting adjuvant therapy for patients with stage II CRC.

TREATMENT OF LOCALIZED RECTAL CANCER

The treatment of rectal cancer presents different challenges, but also different opportunities, compared to colon cancer. Given the location of the rectum within the narrow bony pelvis surrounded by the urogenital organs, large blood vessels, and autonomic nerves, and its proximity to the anal sphincters, rectal cancer surgery is technically challenging, potentially associated with perioperative complications, and often followed by loss of urinary, sexual, and bowel function that permanently impairs quality of life. In addition, rectal cancer has been associated with a higher rate of local recurrence after curative-intent surgery, compared to colon cancer. But the extraperitoneal location of most of the rectum and its proximity to the anal orifice make it accessible to explorations (DRE, endorectal ultrasound [ERUS]) and interventions (external beam radiation therapy, brachytherapy, and local excision [LE]) not currently available for colon cancer.

The selection of the best treatment option for each rectal cancer patient is a complex process and requires consideration of the clinical tumor stage, location of the tumor within the rectum, the impact of treatment upon anorectal and genitourinary function, and the consequences for the patient in terms of prognosis and quality of life. Some rectal cancers can be treated with LE. Others require a transabdominal resection (TAR) of the rectum, with or without sphincter preservation. Finally, many rectal cancer patients require chemotherapy and radiation to reduce the risk of local recurrence and distant metastasis.

Anatomy of the Rectum

The rectum represents the distal portion of the large bowel, extending from the rectosigmoid junction – the area where the tenia coli (characteristic of the sigmoid colon) splay and become the longitudinal muscular layer of the rectum – to the anorectal ring, a palpable anatomical landmark that corresponds to the imprint of the puborectalis muscle on the bowel wall. The anal canal extends from the anorectal ring to the anal verge, the palpable groove between the distal edge of the internal sphincter and the subcutaneous portion of the external sphincter (Fig. 68-11). For practical purposes and standardization, the rectum is defined in terms of distance in centimeters from the anal verge. The distance of a tumor from the anal verge is best measured using a rigid proctoscope, which allows the simultaneous visualization of the anal verge and the centimeter marks on the outside of the scope. In European countries, tumors with the distal edge located within the last 15 cm of the large bowel are considered rectal cancers; in the United States, the limit is 12 cm. The location of tumor in relation to the peritoneal reflection and the promontory, and its distance from the anal verge, can also be determined by MRI, in particular sagittal views.

The mesorectum is the visceral mesentery of the rectum containing the terminal branches of the superior rectal vessels and the rectum's lymphatic drainage. The upper portion of the rectum is located above the anterior peritoneal reflection; it is covered with peritoneum in the front and on both sides, and has a posterior mesorectum attached to the concavity of the sacrum, which is a continuation of the mesentery of the sigmoid colon. Below the peritoneal reflection the rectum is completely extraperitoneal and fully surrounded by the mesorectum. The mesorectum is covered by a thin, glistening membrane called the mesorectal fascia (MRF). Posteriorly, the mesorectum is separated from the presacral fascia by an avascular plane of loose areolar tissue that is the natural plane of dissection during a radical proctectomy. Anteriorly, the mesorectum is separated from the urogenital organs by a remnant of the fusion of two layers of the embryologic peritoneal cul-de-sac known as Denonvilliers fascia – an important anatomical landmark in rectal cancer surgery. Below the peritoneal reflection, the lateral ligaments connect the mesorectum to the pelvic sidewall. The mesorectum tapers off distally as the rectum funnels toward the anorectal ring, where the longitudinal layer of the muscularis propria becomes the internal anal sphincter.

Figure 68-11. Anatomy of the rectum. **A:** Coronal pelvis. **B:** Sagittal pelvis.

The blood supply of the rectum comes primarily from the superior rectal artery, which is the terminal branch of the inferior mesenteric artery after it gives off the left colic artery. The superior rectal vein has a parallel course to its homonymous artery, and joins the left colic vein to form the inferior mesenteric vein draining into the splenic vein. The lower portion of the rectum and the anal canal also receive blood supply from the internal iliac vessels through the middle rectal artery, an inconsistent branch of the inferior vesical artery; the inferior rectal artery is a branch of the pudendal artery. The middle and inferior rectal vessels anastomose with the upper rectal vessels, supplying enough blood to the entire rectum. As in other locations, the middle and inferior rectal veins follow the course of the homonymous arteries, draining into systemic circulation through the internal iliac veins.

The anatomy of the autonomic pelvic nerve system is very important when operating in the rectum, because of its proximity to the plane of dissection during different parts of the operation. Damage to these nerves can result in urinary and/or sexual dysfunction. The hypogastric plexus, located in front of the aorta, contains predominantly preganglionic sympathetic fibers originating from the lumbar sympathetic trunk. The fibers of the hypogastric plexus converge at the level of the aortic bifurcation into well-defined hypogastric nerves, which course laterally and anteriorly over the internal iliac vessels toward the lateral pelvic sidewall. There they join the splanchnic pelvic nerves, containing primarily postganglionic parasympathetic fibers from the anterior rami of S2, S3, and S4, to form the pelvic plexus. Branches of the pelvic plexus provide innervation to the distal ureter, the vas deferens, the seminal vesicles, urinary bladder, and prostate. Branches of the pelvic plexus also provide innervation to the distal rectum, passing through the lateral rectal ligaments, or lateral stalks. Finally, distal to the lateral rectal ligaments, the distal pelvic plexus forms the urogenital neurovascular bundles that pass close to the posterolateral aspect of the seminal vesicles or the vagina, extending toward the apex of the prostate and the neck of the bladder.

Clinical Staging of Rectal Cancer

The preoperative evaluation of the rectal cancer patient follows the same principles as that of the colon cancer patient, but the wider spectrum of therapeutic options for rectal cancer patients requires accurate

information about the location and stage of the tumor. The clinical stage is important in making treatment decisions, such as the intent of the treatment (palliative or curative), the need for neoadjuvant therapy, or even the extent of the surgery (LE vs. TME).

Figure 68-12. Endorectal ultrasound. Role in rectal cancer staging.

Patients with rectal cancer should undergo a complete colonoscopy because synchronous polyps are present in up to 30% of patients, and synchronous cancers in up to 5.3% of patients. They also require a CT scan of the chest, abdomen, and pelvis to exclude distant metastasis, which is present in 20% of patients at the time of diagnosis.

The preoperative locoregional staging of rectal cancer follows the clinical TNM system, based on depth of tumor penetration in the rectal wall and the presence of regional lymph nodes. However, the preoperative assessment of rectal cancer goes beyond determination of clinical tumor stage; it includes the distance of tumor from the anal verge, its relationship to the sphincter complex and the levator muscles, the proximity of tumor to the MRF, and the presence of extramural venous invasion (EMVI). This information is essential in planning treatment and surgery. Gross morphologic features such as size, morphology, and ulceration have been associated with prognosis. However, when stratified by stage, these characteristics have not appeared to contribute independently to oncologic outcomes, and therefore they are not incorporated into treatment decisions.

3 DRE and proctoscopy provide the surgeon with the first direct impression of the tumor. Tumor mobility on DRE provides a gross estimation of the tumor depth of invasion. There is a four-category clinical classification of rectal tumors, based on mobility on DRE, which supposedly corresponds to the four T categories of the TNM system. However, the correlation between the clinical and pathologic T classifications is not very accurate, and varies significantly with the experience of the examiner. In general, DRE is able to distinguish between mobile tumors, most likely limited to the bowel wall, and tethered or fixed tumors, likely penetrating beyond the bowel wall. However, DRE fails to identify more than 50% of pathologically proven involved nodes.¹⁵⁷ Finally, only very distal tumors are within reach of the examining finger. Therefore, pretreatment clinical staging requires imaging studies; namely, ERUS, multidetector CT (MDCT) scan, and MRI.

Ultrasound with an endorectal rotating probe is the imaging modality that best depicts the different layers of the bowel wall, and it is most useful for staging early rectal cancer (Fig. 68-12).¹⁵⁸ But ERUS has a relatively short focal range, and cannot depict important anatomical structures such as the MRF. MDCT scans provide accurate images of the rectum, adjacent pelvic structures, and even the MRF, but have lower tissue resolution compared to MRI. A CT scan of the chest, abdomen, and pelvis should be performed in every rectal cancer patient to exclude distant metastases. MRI with a surface phased-array coil has become the preferred imaging modality for locoregional staging of rectal cancer. Using various sequences and multiple planes, MRI provides high-tissue resolution and excellent anatomical depiction of the rectum, the mesorectum, the MRF, the levator muscles, and other pelvic structures, relative to

tumor location (Fig. 68-13).¹⁵⁹ The addition of new contrast agents and advanced functional sequences such as diffusion-weighted imaging (DWI) and dynamic contrast enhancement (DCE) permit the quantification of tumor biologic processes such as microcirculation, vascular permeability, and tissue cellularity. While still experimental, these images are potentially useful for early assessment of rectal cancer response to neoadjuvant therapy.^{160,161}

Comparative studies suggest that ERUS is at least as accurate as MRI and more accurate than CT scan in assessing the depth of tumor penetration in the bowel wall. The accurate detection of involved mesorectal lymph nodes remains a challenge for all three techniques, however. Two meta-analyses of a number of case series assessing the accuracy of these three techniques reported a wide range of sensitivities and specificities for each, reflecting not only differences in technology, but also wide variation in the criteria used to define malignant lymph nodes.^{162,163} However, the older studies included in these analyses were conducted before MRI techniques for rectal cancer staging were fully developed. At this time, MRI with a rectal cancer protocol provides the most useful information in a majority of rectal cancer patients, and has great utility for surgical planning, while ERUS is most useful for staging early-stage tumors.

Figure 68-13. Magnetic resonance imaging. Role in rectal cancer staging.

Tumor distance from the MRF – the CRM when performing TME surgery – has prognostic implications for local recurrence and patient survival, and has become one of the most important parameters in the preoperative evaluation of rectal cancer patients.¹⁶⁴ MRI is the most accurate imaging modality in determining the distance of the tumor to the MRF, and predicting CRM involvement. The MERCURY trial, a prospective observational study assessing the accuracy of MRI in predicting a curative resection in rectal cancer, reported 92% specificity in predicting a negative CRM.¹⁶⁵ Other important tumor features accurately assessed by MRI, and associated with patient outcomes, are extramural spread, EMVI, involvement of the peritoneal reflection, and distance of tumor from the levator muscle and sphincter complex.^{166,167} Using information on these parameters for patients registered to the MERCURY trial, clinicians are able to stratify rectal cancer patients with good prognosis (e.g., clear CRM, no evidence of EMVI, T2 or T3 <5 mm and not involving the intersphincteric plane) with a 3% LR rate and an 85% 5-year DFS after treatment with surgery alone.¹⁶⁸ In European and Scandinavian countries, the information gained from imaging, rather than clinical TNM staging, is used to determine treatment in patients with rectal cancer.¹⁶⁹

4 Tumor response to neoadjuvant therapy has prognostic value, and re-staging after neoadjuvant

therapy is becoming increasingly important in reassessing treatment options and planning the surgical procedure. Some patients with a clinical complete response are now offered alternatives to rectal resection, such as “wait-and-see,” in the context of clinical trials.^{170,171} However, endoscopy and DRE tend to underestimate tumor response to CRT.¹⁷² Morphologic imaging modalities such as ERUS and CT provide a rough estimate of tumor regression, but cannot reliably distinguish post-treatment edema, fibrosis, and necrosis from residual tumor.¹⁷³ Similarly, MRI assessment of tumor response based on the reduction of signal intensity relative to pre-treatment images, that occurs when tumor is replaced by fibrosis, correlates poorly with pCR.¹⁷⁴ Functional studies such as FDG-PET with or without simultaneous CT, are valuable in assessing partial tumor response, but are not sensitive enough to identify pCR.¹⁷⁵ MRI dynamic sequences such as DWI and DCE, which provide an estimate of tissue perfusion and cellularity, are currently under investigation in assessing rectal cancer response to CRT.¹⁷⁶

Local Excision for Early-Stage Rectal Cancer

Selected patients with stage I rectal cancer, those with tumors localized to the bowel wall (T1 or T2) and without involvement of the mesorectal nodes (N0), can be hypothetically cured with a LE of the portion of the rectal wall containing the tumor. This operation spares most of the mortality, morbidity, and bowel, urinary and sexual dysfunction associated with TME. However, the success of LE requires meticulous patient selection. With LE, the mesorectum is not inspected for pathologic nodal staging. Therefore, LE should only be offered to patients with a low risk of nodal metastasis. The selection criteria for LE include: tumor size smaller than 3 cm, involving less than 30% of the circumference of the rectum, mobile on DRE, localized to the submucosa on ERUS, without evidence of metastatic lymph nodes on ERUS and CT or MRI, and no high-risk histologic features (i.e., grade 3 or 4, lymphovascular or perineural invasion).¹⁷⁷

In the past, only tumors located in the distal rectum could be treated with conventional transanal excision (TAE), and LE was recommended only for tumors located within 8 cm from the anal verge. With the use of endoscopic instrumentation and large operating proctoscopes (TEMTM, Richard Wolf Medical Instruments Corp., Vernon Hills, IL; TEOTM, Karl Storz Corp., El Segundo, CA) or single-port devices (TAMIS, Trans-Anal Minimally Invasive Surgery), LE can now be easily performed for tumors located in the mid and upper rectum. However, the benefit of LE is more significant for very distal tumors that otherwise would require a low anastomosis or a permanent stoma. The real benefit of LE for tumors located in the upper rectum is a matter of debate.

Independent of the approach, a full-thickness excision of the portion of the bowel wall involved by tumor, with a 1-cm negative margin is required to avoid local recurrence (Fig. 68-14). The final decision regarding the suitability of LE is made after the pathologic evaluation of the surgical specimen. If the resection margins are positive, depth of invasion is beyond the submucosa (T stage ≥ 2), or the histology reveals high-risk features (grade 3 or 4, lymphovascular or perineural invasion), the patient should be offered immediate salvage TME.

Even in patients with tumors meeting all selection criteria, LE is associated with a higher rate of LR compared to TME. The recurrence rates for T1 tumors treated with LE have been described as up to 23%.¹⁷⁸⁻¹⁸⁰ While some patients who develop LR after a failed LE are candidates for salvage TME, only half of these patients are ultimately cured of their tumors. Recurrences after LE generally present as more advanced tumors, often requiring extended pelvic dissections.^{181,182} The oncologic outcome for these patients is worse than those treated originally with TME; this reinforces the importance of patient selection for this strategy.

Figure 68-14. Local excision of early rectal cancer. **A:** Marking resection margins. **B:** Incision up to mesorectal fascia. **C:** Resection lodge. **D:** Defect closed with interrupted absorbable sutures.

A number of retrospective case series have compared the results of LE versus radical surgery (RS) for patients with early-stage rectal cancer. A cohort study from the National Cancer Database (NCDB) reported a 12.5% LR rate for LE, versus 6.9% for T1 tumors treated with RS ($p < 0.001$). Five-year overall survival was 77.4% for LE versus 81.7% for RS ($p = 0.09$).¹⁸³ Other series have reported similar results.¹⁸⁴ However, comparisons between LE and RS are limited by selection bias, since patients having LE tend to be older, have more comorbid conditions, and lower-lying tumors; whereas patients having RS tend to be younger and healthier with higher-lying – but usually larger – tumors.

A recent systematic review of one small randomized trial and 12 observational studies, including a total of 2,855 patients with T1N0M0 rectal cancer treated by LE (TAE/TEM-TEO) versus RS, showed that LE was associated with lower perioperative mortality (relative risk 0.31, 95% CI 0.14–0.71), major postoperative complications (relative risk 0.20, 95% CI 0.10–0.41), and need for a permanent stoma (relative risk 0.17, 95% CI 0.09–0.30). The LR rate was higher for patients treated with LE, and overall survival significantly lower, compared to patients treated with RS. The relative risk of dying after LE was 1.46 (95% CI 1.19–1.77), which corresponds to 72 more deaths per 1,000 patients at 5 years. Meta-regression showed that the difference in overall survival observed between groups could be explained by the higher use of LE for tumors located in the lower third of the rectum, which is associated with worse prognosis. Survival was similar between groups when only tumors located in the distal rectum were included in the analysis.¹⁸⁵

A number of studies have compared the outcomes of different techniques – conventional transanal excision, TEMS, TEO, and TAMIS – for LE of rectal cancer, with most comparisons limited to conventional TAE and TEMS. A recent meta-analysis of 6 retrospective case series including 927 procedures, reported that TEMS was associated with less specimen fragmentation, less positive resection margins, and lower LR rates. No difference was observed in complication rate.¹⁸⁶

In summary, the literature suggests that LE may be an alternative to TME for patients with small, distal T1N0 rectal cancers, without high-risk histologic features, that would otherwise require a CAA or an APE. Transanal endoscopic techniques may be superior to conventional transanal excision. Patients considering LE should be informed about the potential gains in improved quality of life, but also about the higher risk of LR and the need for salvage surgery.

Patients with T2N0 tumors are not candidates for treatment by LE alone, independent of tumor histologic features. The rate of LR for these patients when treated with LE alone ranges from 13% to 47%, significantly higher compared to similar stage tumors treated with TAR. Five-year overall survival is also significantly lower for patients with T2N0 tumors treated with LE (65% to 67.6%) compared to TAR (76.7% to 81%).^{183,187} A recent survey of the NCDB found that patients with T2N0 tumors treated with LE alone had a higher hazard ratio for death compared to similar patients treated with TAR (1.535, 95% CI 1.283–1.835).¹⁸⁸ Similar results have been reported in an independent cohort from the SEER database.¹⁸⁹ Based on this evidence, LE alone cannot be recommended as an alternative to RS for patients with T2N0 tumor treated with curative intent.

Radiation therapy has been used to reduce the rate of LR in patients with T2N0 rectal cancer treated with LE. A number of retrospective case series have reported 15% to 21% LR rates and 66% to 76.1% 5-year survival rates with LE followed by radiation or chemoradiation for T2N0 tumors.^{190–193} The CALGB 8984 trial investigated the role of LE followed by 5-FU-based adjuvant chemoradiation for patients with T2N0 cancers, reporting a 66% (95% CI, 51% to 84%) overall survival and 64% (95% CI, 51% to 80%) DFS.¹⁹⁴ The trial compared the survival curves of patients with similar stage tumors treated with TME, concluding that LE and postoperative chemoradiation may be an alternative for patients with T2N0 tumors. However, 32% of the patients initially accrued for this trial were ultimately excluded from analysis due to tumor size, inaccurate staging, surgical specimen fragmentation, high-grade histologic features, or involved resection margins. Therefore, the conclusion is applicable only for properly staged early rectal cancers penetrating only into the muscularis propria (pT2), with full-thickness excision negative resection margins, and no high-risk histologic features.

The results of several retrospective studies have suggested that chemoradiation before LE reduces the risk of recurrence to rates similar to those observed in similar stage patients treated with TME alone.^{195,196} However, these studies are limited by small sample size, variable clinical staging criteria and imaging modalities, and the use of different CRT regimens. A retrospective study using the SEER database showed that patients who had undergone neoadjuvant CRT and LE had equivalent oncologic outcomes compared to patients who had a major resection.¹⁸⁹ One prospective trial found that patients with ERUS-staged T2N0 rectal cancer treated with neoadjuvant CRT had similar recurrence and survival rates when randomized to LE or RS. More than one in four patients in the RS arm required a permanent colostomy, and a similar number required a temporary ileostomy.¹⁹⁷ The ACOSOG Z6014 trial, a single arm study investigating the use of 5-FU and oxaliplatin-based neoadjuvant CRT and LE in T2N0 tumors, recently reported a complete pathologic response in 44% of patients.¹⁹⁸ Only 2 (3%) patients had developed recurrence after 4 years of follow-up. The 3-year DFS was 87%, with a 3-year OS of 90%. At the end of the follow-up 70 of 72 patients treated with this approach had organ preservation.¹⁹⁹ In summary, the optimal treatment of T2N0 rectal cancer is TME; LE alone is not an alternative to radical resection in patients treated with curative intent. Postoperative CRT may be an alternative to TME in a patient with a distal clinical stage T1N0 cancer who is unexpectedly found to have a T2 tumor after LE and is interested in preserving the rectum. Neoadjuvant CRT followed by LE may be an alternative for patients with very distal T2N0 tumors interested in organ preservation, who otherwise would require a permanent colostomy.

LE and other forms of local therapy, such as endocavitary radiation, brachytherapy, or electrofulguration, have been used for palliation in patients who have more advanced tumors or are unfit for a major surgical procedure.

Transabdominal Resection for Rectal Cancer

Patient preparation for rectal cancer surgery is similar to that for colon cancer surgery. Stoma marking is particularly important in these patients, as many will require a temporary or permanent stoma. In addition to discuss fertility options with all individuals of child-bearing potential, female patients receiving neoadjuvant radiation who are interested in preserving fertility should consult their gynecologist regarding the possibility of ovarian transposition. Mechanical bowel preparation, antibiotic and thromboembolic prophylaxis are similar to those described for colon cancer patients. Many surgeons recommend a rectal washout immediately before surgery to eliminate exfoliated cancer cells that could potentially implant in the anastomosis and cause LR. In fact, a recent meta-analysis with 5,012 patients found that this practice is associated with a lower incidence of LR.²⁰⁰ On the operative table, the patient should be placed in lithotomy with the legs in stirrups to provide the surgeon with simultaneous access to the abdomen and perineum. It is important to avoid pressure on the bony prominences, which might cause peroneal nerve compression. Patients requiring prolonged

Trendelenburg position during surgery are at risk of compartment syndrome, in particular obese patients and those with peripheral vascular disease. These patients require monitoring of the peripheral pulses, and position changes, to prevent compartment ischemia.

Principles of Total Mesorectal Excision

The principle of rectal cancer treatment is the eradication of the primary tumor and its lymphatic drainage by en bloc removal of the rectum and the mesorectum, following well-defined anatomical planes. This operation, known as total mesorectal excision, or TME, requires dissection under direct vision along the areolar tissue plane situated between the MRF and the presacral fascia (Fig. 68-15). A sharp dissection along this plane is associated with a higher probability of achieving a negative CRM, lower risk of bleeding from inadvertent tearing of the presacral veins, and reduced risk of injuring the hypogastric nerves.¹²⁸

Adequate lymphadenectomy requires division of the lymphovascular pedicle at the origin of the superior rectal vessels, caudal to the branching of the left colic artery from the inferior mesenteric artery (usually defined as low tie). In patients with clinically suspicious nodes at the origin of the inferior mesenteric artery, the lymphovascular control should be extended proximally by dividing the inferior mesenteric artery close to the origin (high tie). In both cases the sigmoidal branches are included in the surgical specimen; therefore, the proximal division of the bowel should ideally be performed at the junction of the descending and the sigmoid colon, incorporating most of the sigmoid colon in the surgical specimen.²⁰¹ As distal tumor extension along the rectal wall is limited, a distal margin of 2 cm of normal bowel wall is considered adequate for most tumors. However, distal spread in the mesorectum may extend farther than intramural spread. Not infrequently, mesorectal deposits are found 3 to 4 cm distal to the lower edge of the tumor. Therefore, for tumors of the upper rectum, the mesorectal excision should be extended to 5 cm distal to the lower edge of the tumor. In these patients the mesorectum should be divided perpendicular to the axis of the rectum. As some of the distal mesorectum is left in the pelvis along with the distal rectal stump, this operation is known as tumor-specific TME (TSME), to distinguish it from the TME performed with dissection carried to the pelvic floor, the rectum divided distal to the end of the mesorectum, and the entire mesorectum included in the surgical specimen.¹²³

Figure 68-15. Total mesorectal excision. A: APR specimen. B: ELAPE specimen. C: Planes of dissection for TME. D: Robotic TME.

Sphincter Saving Procedures

A TSME or a TME is compatible with sphincter preservation by anastomosing the divided end of the descending or the sigmoid colon to the rectal stump. This operation is known as a low anterior resection or LAR (Fig. 68-16). In this operation the rectum is divided distal to the tumor using a stapling device that simultaneously staples and divides the rectum, leaving a short rectal stump. The anastomosis is completed with a circular stapler that brings together the end of the colon to the rectal stump. The re-establishment of the large bowel's continuity by suturing the colon to the anal canal, working through the anus, is known as coloanal anastomosis or CAA (Fig. 68-17). The connection of the colon to the rectum or anal canal can be performed by an end-to-end or a side-to-end connection, or with the creation of a J-pouch reservoir (Fig. 68-18). A tension-free, well-vascularized low colorectal or coloanal anastomosis requires a complete mobilization of the entire left colon with take-down of the splenic

flexure, including division of the inferior mesenteric vein close to the ligament of Treitz. The blood supply to the entire left colon is based on the left branch of the middle colic vessels through the marginal artery.

Figure 68-17. Double stapling technique for low colorectal end-to-end anastomosis.

Many patients undergoing a sphincter-saving procedure report high bowel frequency, urgency, soiling, and inability to defer defecation for 15 minutes.²⁰² This constellation of symptoms is commonly known as low anterior resection syndrome (LARS).²⁰³ The frequency and severity of these symptoms is variable and depends, to some degree, on the location of the tumor and the anastomosis, the patient's prior bowel function, and the use of neoadjuvant or adjuvant therapy.²⁰⁴ Pelvic irradiation, before or after surgery, increases significantly the risk of bowel dysfunction.^{205,206} The anatomical and physiologic factors that contribute to LARS are not completely understood. Anal sphincter pressures are not different in patients with or without LARS. What appears to be different is an exaggerated anal sphincter relaxation to even small volumes of stool within the neorectum.²⁰⁷ Surgeons have tried to overcome this low capacitance of the neorectum – which results from an end-to-end anastomosis – by creating a colonic reservoir: either a colonic J-pouch, or a side-to-end anastomosis. A number of studies have compared the functional outcomes after straight end-to-end anastomosis and a colonic J-pouch. A systematic review of reconstructive techniques after LAR identified 9 trials that randomized a total of 473 rectal cancer patients to either colonic J-pouch or straight end-to-end anastomosis, reporting that short-term bowel function was better for J-pouch compared to straight anastomosis.²⁰⁸ Frequency and

urgency were less prevalent in patients with a colonic J-pouch, but the rate of fecal incontinence was similar in both groups. The only two trials that followed patients for more than 118 months found minimal or no long-term differences between groups. Although the methodology of these studies was very heterogeneous, they do indicate that a colonic J-pouch is associated with a short-term improvement in frequency and urgency, but no apparent long-term benefit, compared to end-to-end anastomosis. The same systematic review found no differences in anastomotic leak rate, or other complications, between groups. Of note, almost one-third of patients with colonic J-pouches often complained of long-term difficulty emptying the rectum, requiring use of laxatives or suppositories.^{209,210} These symptoms are more prevalent when larger pouches are created; therefore, pouch size should be limited to 5 to 6 cm.^{211,212}

Figure 68-18. Reconstructive options after LAR. **A:** End-to-end anastomosis. **B:** End-to-side anastomosis. **C:** J-pouch anastomosis.

The side-to-end anastomosis (created by inserting the anvil of a circular stapler 3 to 4 cm from the end of the mobilized descending colon) can also potentially increase the reservoir capacity of the anastomosis. It has similar functional results, but is easier to construct than the colonic J-pouch; although it, too, is associated with defecatory problems.²¹³ The creation of a transverse coloplasty proximal to an end-to-end anastomosis is another option used to increase the capacity of the neorectum, but is associated with a higher anastomotic leak rate.²⁰⁸

In summary, colonic reservoirs are associated with a temporary improvement in bowel frequency and urgency, but have the risk of long-term defecatory problems. In general, the author prefers an end-to-end anastomosis using the larger descending colon, rather than the sigmoid colon, for creation of the neorectum.

The integrity of the anastomosis should be tested intraoperatively with a pneumatic test, or by endoscopy, with distension of the bowel while submerging the anastomosis in water. Air leaks thus detected may be treated with suture repair, re-do of the anastomosis, and/or the creation of a proximal diverting stoma. Testing the integrity of the anastomosis during surgery has been associated with a lower risk of clinical postoperative anastomotic leak.²¹⁴

Low colorectal and coloanal anastomoses have a risk of leakage ranging from 3% to 34%, depending on the patient population, the use of neoadjuvant radiation, the distance of the anastomosis from the anal verge, and the surgical technique.^{215,216} An anastomotic leak can cause pelvic sepsis, which may not only preclude sphincter preservation, but has also been associated with an increased risk of local recurrence and poorer survival²¹⁷ (although more recent data have questioned this association).^{218,219} To prevent these possible complications, a diverting stoma is recommended for patients having a TME, and for patients receiving neoadjuvant radiation.²²⁰ Diverting stomas do not prevent complications, but mitigate the consequences of a leak and reduce the need for urgent reoperation in patients developing a leak.^{221,222} A loop ileostomy is preferred over a transverse loop colostomy because it is easier to create and close.²²³ However, loop ileostomies are associated with postoperative dehydration and electrolyte abnormalities requiring hospital readmission.²²⁴ Prevention of these complications requires adequate patient education and training about stoma management.

Abdominoperineal Excision

For many cancers located in the distal rectum, particularly those infiltrating the levator muscles or the anal sphincter, an oncologically safe circumferential and/or distal resection margin is not compatible with sphincter preservation. In these patients an R0 resection requires a TME with en bloc excision of the levator muscles and the anal canal, and the creation of a permanent end colostomy. This operation is known as abdominoperineal excision of the rectum or APE (Fig. 68-19). As the name indicates, the APE has two parts: an abdominal part and a perineal part. During the abdominal part, the proximal lymphovascular control, division of the colon, and dissection along the mesorectal plane are similar to those in LAR, except that the mesorectal dissection should stop at the upper level of the levators, to avoid disturbing the portion of the rectum resting on the levator muscles. During the perineal part, the anal canal with the sphincter complex and the levator muscles are dissected off the ischiorectal fat, all the way to the apex of the ischiorectal fossa. The levators are divided close to their insertion in the white line near the obturator internus and coccygeus muscles. The levator muscles are left attached to the rectum, and the resulting surgical specimen has a cylindrical appearance; therefore, this procedure is called cylindrical APE or extralevator APE (ELAPE) (Fig. 68-20).²²⁵ However, some surgeons question the need to entirely remove both levator muscles in every rectal cancer patient, and recommend removing only the portion of the levators required to clear the tumor. This operation has been called the standard APE or SAPE.²²⁶ The choice between an ELAPE and SAPE is controversial. The potential oncologic benefit of larger tissue removal needs to be weighed against the increased morbidity potentially associated with a larger perineal defect, particularly in patients treated with neoadjuvant therapy.²²⁷ A recent meta-analysis with 949 patients from one randomized trial, one prospective case-control study, and six retrospective case series, indicated that ELAPE is associated with lower intraoperative rectal perforation, lower positive CRM, and lower risk of local recurrence, but with similar complication rates, compared to SAPE.²²⁸ At the present time, the hypothetical benefit of the ELAPE over the SAPE has not been proven conclusively. It is possible that both techniques – the total or the tumor-specific excision of the levator muscles – may be equivalent as long as an R0 resection, with an intact rectal specimen, is achieved.

Figure 68-19. Abdominoperineal excision of the rectum (APE).

Figure 68-20. Cylindrical APE.

Many surgeons will perform both parts of the APE operation with the patient in modified lithotomy, also known as the Lloyd–Davis position. It provides relatively good access to the perineum and allows two teams to work simultaneously – one in the abdomen, and one in the perineum. Others perform the abdominal part in the supine position, and the perineal part with the patient prone over a hip roll and padding of the bony prominences. The prone position, also known as jackknife position, provides better exposure of the perineum, and facilitates assistance and teaching. It requires turning the patient, which takes time, and does not allow a two-team approach. Results seem to be similar with both approaches, and the selection is based on the surgeon's preferences.²²⁹

Minimally Invasive Surgery for Rectal Cancer

5 Open surgery for rectal cancer requires long abdominal incisions. An APE can be performed though a midline infraumbilical or low transverse incision. Most sphincter-preserving procedures (SSPs) require a long midline incision, extending from the epigastrium to the symphysis of the pubis, in order to permit access to the entire left side of the large bowel from the splenic flexure to the lower rectum. These abdominal incisions are a source of patient discomfort, and short- and long-term morbidity. The goal of minimally invasive surgery in rectal cancer is to reduce the size of the abdominal incision, thus expediting recovery, without compromising the completeness of the mesorectal excision or the oncologic outcomes. However, the adoption of minimally invasive surgery for rectal cancer has been slow due to the difficulty of working in the relatively deep and narrow pelvic space using long, rigid, nonarticulated laparoscopic instruments. According to a number of retrospective case series and small randomized controlled trials, laparoscopic TME is associated with less postoperative pain, less surgical morbidity, and shorter length of hospital stay, but equivalent completion of the mesorectal excision, CRM positivity, and even LR, compared to open TME.^{230–232} While these studies have shown that laparoscopic TME is feasible, less than 20% of all rectal cancer operations are performed laparoscopically in the United States.²³³

Three large multi-institutional prospective, randomized trials have compared open and laparoscopic TME for rectal cancer (Table 68-9).^{234–236} A fourth prospective study conducted in the United States, the ACOSOG Z6051, has completed accrual, but the results are not available yet. The combined experience of these trials indicates that laparoscopic TME results in longer operative time, less blood loss, faster bowel recovery, and shorter hospital stay compared to open TME. Operative mortality and intraoperative and postoperative complications were not different between groups. The proportions of patients having an SSP, a complete mesorectal excision, or a positive CRM were not different between groups, nor was the number of lymph nodes retrieved. However, conversion and positive CRM rates in the laparoscopic arms varied widely between different studies. These differences could be explained by trial design, inclusion criteria, randomization, and use of neoadjuvant therapy. Only the CLASICC and COREAN trials have reported 3-year oncologic outcomes. LR, distant metastasis (DM) and survival were not different between groups. However, these results should be interpreted with caution, because the CLASICC trial was not specifically powered to detect differences between treatment groups in rectal cancer patients, and the COREAN trial allowed a 15% difference as the noninferiority margin.

Therefore, while these studies justify the use of laparoscopy in rectal cancer, it is prudent to wait for the final results of the larger COLOR II and ACOSOG Z6051 trials before endorsing laparoscopy as the preferred surgical approach to LARC.

Table 68-9 Open versus Laparoscopic Rectal Resections: Results of the Most Representative Series

Open/Laparoscopic	CLASICC ¹²⁻¹⁵ (2005–2007–2010–2013)	COLOR II ^{18,19} (2013)	COREAN ^{20,21} (2010–2014)

Many surgeons currently perform a hybrid approach consisting of the laparoscopic lymphovascular control and colon mobilization, and the open mesorectal dissection and anastomosis through a lower abdominal transverse incision. The hybrid approach is aimed at facilitating the most technically challenging portion of the operation: the dissection of the distal rectum and the creation of the anastomosis. With this approach the size of the abdominal wall incision is smaller compared with a totally open procedure, but larger than with a totally laparoscopic procedure. Although there is some evidence of short-term advantages to this approach compared to open surgery,²³⁷ long-term benefits compared to the totally open or laparoscopic approaches are unknown.

The robotic platform (da Vinci®) was introduced to the surgical armamentarium to facilitate the minimally invasive approach to procedures such as prostatectomy, hysterectomy, and TME, which require optimal visualization and dexterity in the narrow pelvic space. The experience accumulated thus far – based on retrospective institutional case series – suggests that robotic TME is equivalent to laparoscopic TME in terms of completeness of the mesorectal excision, CRM positivity, and short-term oncologic outcomes. Conversion rates appear to be lower compared to laparoscopic TME, but hospital charges are higher.²³⁸ A prospective, randomized study comparing laparoscopic and robotic TME – the Robotic Versus Laparoscopic Resection for Rectal Cancer (ROLARR) trial – has completed accrual, but the results are not available yet.²³⁹ However, as laparoscopy has not become standard in LARC, it is

likely that the controversy regarding the benefit of robotic TME will continue for years.

The transanal–transabdominal proctectomy, or down-to-up TME, is a transanal, minimally invasive approach for the dissection of the distal rectum in patients with a narrow pelvis.^{240,241} With this approach, lymphovascular control, the entire colonic mobilization, and dissection of the upper rectum are performed using conventional transabdominal laparoscopy. The dissection of the distal rectum is performed through the anus, using either conventional transanal equipment for very distal tumors, or endoscopic equipment (TEMS, TEO, TAMIS) for higher tumors. The rectal wall is incised circumferentially, distal to the tumor, and the MRF is identified. The lumen of the colon is closed with a purse-string suture to avoid contamination. The dissection is carried cephalad in the proper plane until the abdominal field is reached. The specimen is then removed, and the anastomosis performed through the anus. This approach is particularly useful for patients with very distal rectal cancers treated with chemoradiation therapy, in which the surgeon has no anatomical cues about where to transect the rectum in order to achieve a negative distal margin. The transanal approach allows the surgeon to choose precisely the point for transecting the rectum while visualizing the distal edge of the tumor. The benefit of the down-to-up approach for higher rectal cancers that could be treated with a conventional transabdominal dissection and a double-stapled anastomosis are uncertain.

Adjuvant Chemoradiation for Locally Advanced Rectal Cancer

Several randomized, controlled trials conducted in the pre-TME era demonstrated that radiation therapy (RT) given before or after surgery reduced the rate of LR, compared to surgery alone.^{242–244} However, the relevance of these trials was later questioned, because surgery was not standardized and the LR rates reported in the control arms – approximately 25% – were considered too high compared to that of patients treated in later years with surgery alone according to TME principles.¹²⁹ The efficacy of RT in the setting of quality TME surgical resection was investigated in the Dutch Colorectal Cancer Group trial, which randomized 1,861 patients with resectable disease to TME alone or short-course RT (SCRT) (5Gy a day × 5 days, for a total dose of 25Gy), followed by TME within 2 to 7 days. The study showed that SCRT reduced the rate of LR in resectable rectal cancer treated by TME, compared to TME alone; however, SCRT did not provide a significant survival benefit.²⁴⁵ This trial proved that preoperative RT decreases the rate of LR in LARC patients treated with TME surgery.

The benefit of combining chemotherapy with RT was proven by several randomized trials that compared postoperative RT combined with 5-FU, administered as a bolus or as continuous venous infusion (CVI), to postoperative RT alone, in patients with pathologic stage II and III rectal cancer.^{246,247} The results proved that combined 5-FU and radiation was more effective than radiation alone in reducing the risk of LR, and that CVI 5-FU was associated with lower toxicity compared to bolus 5-FU.

The European Organization for Research and Treatment of Cancer (EORTC) protocol 22921 was developed to assess the effect of adding CT to preoperative RT, and the subsequent value of postoperative CT in rectal cancer patients.²⁴⁸ At the 5-year mark, LR was significantly lower in all three arms receiving any CT (pre- or postoperative) compared to preoperative RT alone, indicating a benefit of CT in reducing the risk of LR, regardless of when it was administered. The addition of CT to RT did not impact survival. Additional work by the Federation Francophone de la Cancerologie Digestive corroborated these findings.²⁴⁹ These studies showed that, similar to what was found using postoperative radiation, adding CT to preoperative RT also reduced the rate of LR, compared to preoperative RT alone.

The German Rectal Cancer Group (CAO/ARO/AIO 94) compared preoperative versus postoperative CRT in 823 patients with clinical T3–4/N+ rectal cancer.²⁵⁰ RT in this trial consisted of 50.4 Gy in 25 fractions with bolus 5-FU as a radiosensitizer. In the preoperative treatment group, surgery was performed 6 weeks after completion of CRT. Both groups had surgery according to TME principles, and received postoperative adjuvant CT. The preoperative CRT group had less toxicity and lower 5-year LR rates compared to the postoperative CRT group (6% vs. 13%). This study found no differences in the rates of DR, DSS, or OS. The NSABP R-03 study also compared the use of preoperative versus postoperative 5-FU/LV, using 45 Gy in 25 fractions in T3/4, N+ patients, to evaluate differences in DFS, LR, or OS.²⁵¹ Despite stopping the study early due to limited accrual, the R-03 study reported better DFS in the preoperative CRT group, compared to the postoperative group, with a near-significant difference ($p = 0.065$) in OS and no difference in LR. The results of these two trials established preoperative CRT as the preferred treatment for LARC in both Europe and the United States.

More recently, it has been shown that capecitabine is noninferior to infusional 5-FU as a

radiosensitizer for LARC, in both the NSABP R-04 trial and the German Cancer Research Center multicenter trial.^{252,253} Several large, prospective trials have failed to prove that the addition of oxaliplatin to a fluoropyrimidine (5-FU or capecitabine) is superior to fluoropyrimidine alone as a radiosensitizer in patients with LARC.^{252,254–256} In fact, patients receiving the oxaliplatin plus a fluoropyrimidine had a greater rate of adverse events, with similar or lower tumor response rates. Therefore, based on the current evidence, oxaliplatin is not recommended as a radiosensitizer to a fluoropyrimidine in patients with LARC.

In addition to the standard hypofractionation (180 to 200 cGy a fraction) commonly delivered during the standard CRT, radiation therapy is also frequently delivered as short course (SCRT) using fewer, larger fractions (5 Gy daily fractions for 5 consecutive days and a total dose of 25 Gy). In these patients, surgery is performed within 7 days of completion of the radiation. Both schemes are biologically equivalent in eradicating cancer cells, but SCRT has the potential benefits of shorter duration of treatment, more efficient utilization of resources, and reduced cost compared to CRT. However, higher dose per fraction increases the risk of delayed toxicity, and tumor regression is lower with SCRT. Two prospective, randomized trials comparing SCRT with CRT have reported equivalent local tumor control with both regimens, and the selection between CRT and SCRT is based on doctor and patient preferences.^{257,258} In general, CRT is preferred in the setting of large tumors that may benefit from maximal tumor regression before surgery.

Current guidelines recommend CRT with the aim of reducing the risk of LR for all patients with stage II and III rectal cancer. However, the risk of LR is variable depending on the distance of the tumor from the anal verge, the risk being lower for tumors located in the upper rectum compared to those in the lower rectum. It is possible that some patients with high rectal cancers, specifically those with T3N0 tumors and a clear CRM, may not actually benefit from preoperative radiation but may simply be exposed to radiation-associated toxicity. A current trial in the United States seeks to address this question by comparing the outcomes of rectal cancer patients treated with neoadjuvant chemotherapy, with or without radiation, before TME.²⁵⁹

Adjuvant Chemotherapy for Locally Advanced Rectal Cancer

In the past, LR was the dominant problem in patients with LARC, but in the modern era more patients develop distant metastasis than LR. Consequently, patients with LARC treated with neoadjuvant CRT and TME are recommended for postoperative adjuvant chemotherapy, with the aim of reducing distant metastasis and improving survival. However, the data supporting this recommendation are limited, and based heavily on experience using adjuvant therapy for resected colon cancers. The QUASAR study discussed above showed that adjuvant chemotherapy has a modest effect in lowering recurrence and improving survival in stage II/III CRCs following curative-intent surgery.¹⁵³ However, the cohort was not powered to demonstrate differences in the 29% of rectal cancer patients who were accrued, and the association with better outcomes stems from subset analysis. In contrast, the 10-year update of the EORTC 22921 trial showed no difference in OS or DFS with the addition of 5-FU–based postoperative chemotherapy in rectal cancer patients treated with preoperative RT or CRT and TME.²⁶⁰ However, these results have been criticized because the proportion of patients receiving the full dose of postoperative adjuvant chemotherapy was only 43%, thus underestimating the therapeutic effect. A meta-analysis of 21 controlled trials in patients receiving potentially curative surgery, including a total of 4,854 patients randomized to surgery plus fluoropyrimidine-based postoperative chemotherapy, and 4,367 patients to surgery and observation, has shown a significant reduction in the risk of death (17%) (HR = 0.83, CI: 0.76–0.91) and a reduction in the risk of DR (25%) (HR = 0.75, CI: 0.68–0.83) among patients undergoing adjuvant chemotherapy, compared to those undergoing observation.²⁶¹ Available data were insufficient to investigate the effect of adjuvant chemotherapy separately in different TNM stages. These data support the use of postoperative chemotherapy after curative-intent surgery in patients with rectal cancer. Similar to colon cancer patients, patients with LARC treated with CRT and TME are recommended to receive 5-FU or capecitabine plus oxaliplatin-based adjuvant chemotherapy. The length of adjuvant treatment in rectal cancer is shorter compared to colon cancer (4 months vs. 6 months), given the use of sensitizing 5-FU or capecitabine during CRT.

A common criticism about the use of postoperative adjuvant chemotherapy after curative surgery in patients with rectal cancer is low treatment compliance. In some series, up to 27% of eligible patients never start treatment, and more than 50% require dose reductions or treatment interruptions or delays.^{248,256} This is particularly relevant, as a systematic review of 10 studies – including more than 15,000 patients – evaluated the effect of timing on the efficacy of postoperative adjuvant therapy,

demonstrating that each 4-week delay in treatment correlated with a 14% decrease in OS.²⁶² The low compliance with postoperative adjuvant chemotherapy has been attributed to postoperative complications, slow recovery after surgery, delays due to closure of the temporary ileostomy, or simply patient refusal. Delivering systemic chemotherapy before surgery has the potential advantage of increasing treatment compliance, potentially enhancing the efficacy of CT in preventing DM, and ultimately improving survival. In addition, it increases response of the primary tumor, and shortens the time to temporary ileostomy reversal. A number of studies have shown that compliance with systemic chemotherapy is higher when it is delivered before CRT and TME, compared with conventional postoperative adjuvant chemotherapy in patients LARC patients who are candidates for curative surgery.^{263–265} Although solid data from large prospective studies are still lacking, in the most recent edition of the NCCN guidelines neoadjuvant chemotherapy before CRT and TME is contemplated as an option in the treatment of LARC patients.

Outcomes of Multimodality Treatment in Patients with Locally Advanced Rectal Cancer

Perioperative mortality in patients undergoing multimodality therapy, including total mesorectal excision for LARC, ranges from 1% to 3.5%, and between 23% and 48% of patients develop perioperative complications.^{250,266,267} Sepsis is the most common complication after rectal cancer surgery. A recent systematic review of the literature, including 53 prospective cohort studies and 45 randomized trials, found a 2% postoperative death rate, 7% rate of surgical wound infection, 11% rate of anastomotic leakage, and a 12% rate of pelvic sepsis.²⁶⁷ In addition to pelvic sepsis, perineal wound dehiscence is the most common complication after APE. In a large systematic review of 32 studies, the rate of perineal wound complication was 15.3% for patients treated with surgery alone, and 32% in those treated with surgery and RT.²²⁷ Many of these patients also had pelvic sepsis. The proportion of patients with perineal complication was similar for those who had ELAP: 14.8% for surgery alone and 37.6% for surgery and radiation. The rate of perineal hernia was also similar for patients treated with SAPE and ELAPE: 1.8% versus 2%. Other common postoperative complications include urinary retention, pneumonia, and thromboembolic disease.

Surgery for rectal cancer, particularly when combined with CRT or SCRT, has iatrogenic long-term consequences including urinary, sexual, and bowel dysfunction. Up to 39% of patients develop urinary complications, 45% sexual dysfunction, and even a larger proportion, bowel dysfunction.^{268,269} A recent population-based study found a 26% rate of moderate bowel problems, 17% urinary dysfunction, and 25% severe problems with sexual function among patients treated for rectal cancer. Patients with a stoma were more likely to have difficulty with body image and sexual activity compared to patients with no stoma. Less than 30% of rectal cancer patients reported perfect health; rectal cancer patients were more likely to report problems, compared to patients with colon cancer. A follow-up study of the Dutch TME trial recently reported that these treatment-related symptoms persist 14 years after treatment; they reported increased sexual dysfunction, and a small decrease in overall functioning, as measured by a variety of quality of life questionnaires distributed to the general population.²⁷⁰

Algorithm 68-1. Approach to rectal cancer according to clinical staging.

Contemporary cohorts of stage II/III rectal cancer treated with neoadjuvant CRT, TME, and postoperative chemotherapy have mostly reported 5-year LR rates between 5% and 10%, 5-year DFS of around 60%, and 5-year OS around 70%.

Treatment Selection in Patients with Localized Rectal Cancer

Unlike patients with localized colon cancer, who all require oncologic resection as the initial form of therapy, patients with rectal cancer have multiple treatment options. The selection among different options depends primarily on the clinical stage of the tumor, as determined by DRE, proctoscopy, and imaging studies, on the distance of tumor from the anal verge, and on patient performance status and expectations.

The standard treatment for patients with stage I rectal cancer (T1N0 or T2N0) is TME, but LE has increasingly been chosen as a reasonable and acceptable alternative for patients with distal T1N0 tumors. CRT and LE may also be considered as an alternative to TME in patients with T2N0 tumors interested in sphincter preservation, in whom a TME would require a permanent colostomy.

More advanced tumors – those penetrating beyond the muscularis propria (T3–4, any N) and/or involving the regional lymph nodes (any T, N+), and without evidence of distance metastasis – have several treatment options. In the United States and many other countries, where decisions regarding the treatment of rectal cancer are based on clinical TNM staging, patients with locally advanced disease are treated with 5-FU or capecitabine-based CRT, followed by TME, with consideration given to FOLFOX prior to CRT as an acceptable option (Algorithm 68-1).

In Europe and Scandinavia, where rectal cancer patients are stratified into different risk categories based on MRI features, patients are recommended for different treatment approaches according to their individual risk category (Algorithm 68-2). The MRI-based risk stratification system uses a number of features, such as the proximity of the primary tumor to the MRF, the depth of tumor penetration into the mesorectum, the presence of large venous invasion, and the presence of metastatic lymph nodes.¹⁶⁸ Based on these features, they have developed a three-tier classification scheme that includes low risk (the good), intermediate risk (the bad), and high risk (the ugly); each group with a different risk of relapse, and therefore requiring different treatment strategies.^{169,271} The low-risk group is recommended TME alone. The intermediate group is recommended SCRT followed by TME, while the high-risk group is recommended neoadjuvant CRT followed by TME. This treatment approach, guided by MRI risk categorization, is based mainly on results of prospective observational studies conducted in institutions with significant expertise in rectal cancer, but has not yet been tested in prospective, randomized trials.

Algorithm 68-2. Approach to locally advanced rectal cancer based on a three-tier risk stratification system (“the good, the bad, and the ugly”).

For patients requiring a TME, the decision between an APE and an SSP depends on the relationship of the tumor with the anal sphincter and the levator muscle. In general, an APE is required when the tumor directly involves these structures, or is so close to the sphincter that resection with a negative resection margin will result in a loss of sphincter function. In borderline cases, baseline anal sphincter and bowel function, as well as patient wishes and desires should be taken into consideration. The patient should be counseled about LR rates and expected long-term surgical outcomes.

TUMOR-RELATED EMERGENCIES

Between 15% and 30% of all CRC patients present as surgical emergencies, obstruction (78%) being the most common presentation, followed by perforation (10%) and bleeding (4%).^{272–274} Chronic bleeding leading to severe anemia is common, particularly in right-sided tumors; but acute hemorrhage requiring surgical or endovascular intervention is infrequent. Obstruction is the presenting symptom in more than 15% of patients diagnosed with CRC, and CRC is responsible for more than 50% of all cases of acute colonic obstruction.²⁷⁵ Rectal cancers seldom present as an emergency (5.9%); this is much more likely with colon cancers (21.7%),²⁷³ most of which are in the left colon where the feces are solid, the lumen is smaller, and tumors are more likely to be annular. Large bowel obstruction may be secondary to other conditions such as diverticular disease and volvulus, which are the differential diagnosis of CRC.

The obstructed bowel undergoes significant changes in motility, secretion, and blood flow, which are responsible for the clinical manifestations. Proximal to the obstructed segment, particularly in left-sided obstructions, the colon develops mass action contractions, which cause colic pain. Persistent obstruction and progressive distension lead to colonic hypomotility. Colonic obstruction causes progressive abdominal distension as a result of the accumulation of gas (mostly nitrogen from swallowed air), increased fluid secretion, and hyperproliferation of anaerobic bacteria. The accumulation of fluid in the distended colon can lead to dehydration. Progressive distension in the presence of a competent ileocecal valve results in a closed-loop obstruction. The increase in intraluminal pressure can compromise the mucosal blood flow and lead to irreversible ischemia. Tension in the wall of the distended bowel increases in proportion to the fourth power of the radius; the risk of ischemia and subsequent perforation is therefore high, particularly in the cecum, the segment of colon with the largest diameter.²⁷⁶ The risk of perforation is related not only to the caliber of the colon, but also to the onset of obstruction (higher risk when acute) and the duration of the obstruction. Mucosal ischemia has been implicated as the cause of a nonspecific form of colitis that, in some patients, develops proximal to the site of obstruction. The presence of ischemia, which can only be diagnosed at the time of surgery, should influence the extent of resection.

Acute colonic obstruction manifests as abdominal discomfort or frank pain (depending on the onset of the obstruction), reduction or complete cessation of the passage of flatus and feces, and progressive abdominal distension. Abdominal tenderness, particularly if associated with fever and leukocytosis, requires immediate evaluation to exclude perforation or ischemia. DRE reveals an empty rectum in most patients with large bowel obstruction.

Colonic obstruction must be distinguished from pseudo-obstruction. While the symptoms are similar, colonic pseudo-obstruction often presents in a specific clinical setting (patient immobilization, use of opioids, electrolyte imbalance), is still associated with passage of small amounts of stool and flatus, and is not associated with tenderness.²⁷⁷ However, definitive diagnosis often requires specific radiologic tests, such as a water-soluble contrast enema or CT.

A plain abdominal film demonstrates colonic distension, with air-fluid levels, and a cut-off at the site of obstruction. The absence of small bowel distension indicates a competent ileocecal valve, with an increased risk of cecal perforation. The presence of gas in the small bowel and rectum raises the possibility of ileus or colonic pseudo-obstruction, but radiologic findings can be misleading. The presence of intramural gas indicates advanced ischemia. A chest radiograph should always be obtained to exclude the presence of pneumoperitoneum.

A water-soluble contrast enema may help to determine the degree and level of obstruction. The flow of contrast to the cecum and the absence of mucosal abnormalities suggest pseudo-obstruction. The osmotic effect of the water-soluble contrast material may have a therapeutic effect in decompressing the colon in these patients.²⁷⁸ The mucosal detail at the site of obstruction may help to define the cause of obstruction. However, endoscopy is a better alternative to contrast enema when confirming the presence of cancer. CT of the chest, abdomen, and pelvis often locates the transition point between the distended bowel above the obstruction and the collapsed bowel distal to that point. It also helps define the cause of the obstruction and, if malignant obstruction is confirmed, it is useful in staging the tumor.²⁷⁹

When compared with elective surgery, patients requiring emergency surgery have more advanced disease. Even when stratified by stage, however, survival is worse for patients undergoing emergency surgery.^{273,280} Also, an R1 resection is 10 times more likely for patients receiving emergency surgery.²⁸¹

Patients presenting with obstructing CRC have higher operative mortality and morbidity and a poorer long-term prognosis than patients undergoing elective resection.^{274,282} Perioperative mortality is three times higher in surgery performed for obstruction, compared with elective surgery.²⁷⁴ Cardiopulmonary

complications and abdominal sepsis are the major causes of in-hospital mortality and morbidity. The aim of surgery is therefore to minimize morbidity while obtaining functional results similar to those obtained for patients undergoing elective resection.

Patients with colonic obstruction are often dehydrated, and require preoperative fluid resuscitation and correction of electrolyte imbalances before surgery. A urinary catheter facilitates fluid management. Unstable patients should be monitored appropriately in the intensive care unit. A nasogastric tube prevents accumulation of swallowed air. Given the large fecal load proximal to the point of obstruction, antibiotic prophylaxis with a second-generation cephalosporin or a combination of an aminoglycoside and metronidazole should be given at the time of surgery.

The surgical management depends on the location of the obstruction. Lesions proximal to the splenic flexure are commonly treated by an extended right hemicolectomy, with primary anastomosis between the terminal ileum and the nonobstructed colon distal to the lesion. This is a single procedure that removes the entire segment of distended and potentially ischemic bowel, and eliminates the risk of leaving a synchronous tumor in the obstructed colon. Some of these patients develop mild diarrhea, which is usually temporary.

The management of a lesion located distal to the splenic flexure is more controversial. The earlier described three-stage procedure is rarely used today (1 – Diverting colostomy, 2 – Tumor resection and anastomosis, 3 – Colostomy closure). A safe choice is the two-stage procedure, with initial resection of the segment containing the tumor, closure of the rectal stump as a Hartmann pouch, and construction of an end colostomy, followed by bowel anastomosis at a later date. However, the cumulative mortality and morbidity of both procedures is significant, and at least 30% of patients are left with a permanent colostomy.²⁸³ In most tertiary centers, this operation is now limited to situations in which a primary anastomosis is contraindicated (e.g., extensive peritoneal contamination and/or severe sepsis).

The goal of surgery today is to relieve the obstruction and treat the cancer in a single operative procedure. Options include: (1) self-expanding metallic stents (SEMS) as a bridge to elective segmental colon resection, (2) subtotal colectomy and ileorectal anastomosis, (3) segmental colon resection, intraoperative colonic lavage, and primary anastomosis.

The rationale for the use of SEMS is temporary relief of the obstruction, avoiding the morbidity associated with an emergency operation, allowing medical stabilization, full staging work-up, one-stage surgery with primary anastomosis, and a minimally invasive approach. Most of the experience with this method comes from retrospective case-series studies; the success in relieving the obstruction ranges from 40% to 100%.²⁸⁴ SEMS also has associated complications, such as re-obstruction (12%), migration (11%), and perforation (4.5%).²⁸⁴

Several randomized, controlled trials comparing SEMS with emergency surgery have been published, with conflicting results.²⁸⁵⁻²⁸⁹ Overall, the clinical success rate of relieving obstruction with SEMS ranges from 40% to 97%. It is important to recognize that the overall complication rate across these trials is variable (8.3% to 35%) and a recent prospective trial conducted in the Netherlands was stopped prematurely, due to an increased number of colonic perforations in the SEMS arm.²⁸⁹ Perforation from the use of stents may result in a shorter DFS.²⁹⁰

A subtotal colectomy with ileorectal anastomosis is a quick operation in which nondistended bowel is used for the anastomosis. This procedure minimizes the risk of fecal spillage, eliminates the risk of missing a synchronous tumor in the obstructed portion of the colon, and facilitates surveillance. The disadvantages, however, include a higher incidence of bowel obstruction after ileorectal anastomosis and the development of postoperative diarrhea, which may become incapacitating in elderly patients.²⁹¹

A segmental resection with intraoperative colonic lavage and primary anastomosis avoids the risk of postoperative diarrhea, but carries a risk of fecal spillage and missing synchronous tumor. In addition, it requires using previously obstructed bowel for the construction of the anastomosis. Surgical tradition has condemned the performance of an anastomosis in an unprepared colon. Experience accumulated from the management of patients with civilian colon trauma has demonstrated that, under specific circumstances, a primary anastomosis can be performed safely in an unprepared colon, provided the bowel appears healthy and there is no extensive soiling in the peritoneal cavity. This experience has been transferred to the treatment of malignant colonic obstruction. Therefore, a segmental resection with colonic lavage and primary anastomosis is a viable option, as long as the colon is not ischemic and there is no spillage during the operation. The use of a temporary diverting ileostomy may be necessary, but when the safety of a primary anastomosis is questionable, a staged procedure with a segmental resection, a Hartmann pouch, and an end colostomy, may be preferable.²⁹²

SURVEILLANCE AFTER CURATIVE RESECTION FOR COLON AND RECTAL CANCER

Of the almost 1 million patients diagnosed with CRC worldwide every year, two-thirds have curative intent surgery, but ultimately one-third of them will develop recurrence of disease or a second colorectal primary. Most recurrences arise within 3 years of the initial treatment, and almost all arise within 5 years. Recurrences are usually diagnosed at an advanced stage and have an ominous prognosis. Surveillance regimens aim to identify recurrences before they become symptomatic, and while they are still potentially resectable.^{293,294} Several meta-analyses of prospective, randomized trials comparing intensive or minimal surveillance after curative resection in patients with stage I to III CRC suggest that recurrences were diagnosed earlier and surgical salvage was more likely in patients undergoing intensive surveillance.^{293,295} The survival benefit can only be partly attributed to the improved ability to resect recurrences; other elements such as increased psychological support, behavior modifications, and better treatment of comorbid conditions that accompany intensive surveillance regimens are also thought to contribute to improved survival. Based on this evidence, cancer organizations have established guidelines for surveillance after curative resection of CRC. All of them include a combination of regular history and physical examination, determination of CEA level, endoscopy, and imaging of the chest, abdomen, and pelvis (Table 68-10). Some clinicians recommend surveillance for stage II/III disease, while others also include stage I. In the future, surveillance will be risk-adapted, targeting patients more likely to benefit from intensive surveillance based on clinical and molecular prognostic factors. Despite these recommendations, a recent population-based cohort study of 57 patients concluded that 70% were diagnosed between scheduled examinations.²⁹⁴

TREATMENT OF STAGE IV COLON AND RECTAL CANCER

Between 20% and 34% of all CRC patients have metastasis at the time of diagnosis; these are known as synchronous metastases. Another one-third of patients will develop metastasis sometime after undergoing treatment of the primary disease; this is known as metachronous metastasis. Synchronous metastases are usually more extensive and, in general, carry a worse prognosis compared to metachronous metastases.

The liver is the most common site of CRC metastasis, and liver metastasis is the most common cause of cancer death in patients with CRC. Autopsy studies have revealed that 50% of patients dying from CRC have liver metastasis and, in one-third of them, the liver is the only site of metastatic disease.²⁹⁶ Some patients with liver-only metastatic disease are resectable at the time of diagnosis. Others are not resectable, due to the involvement of critical structures by large volume of metastatic disease. The treatment of stage IV CRC patients is complex, and requires consideration of the number of organs involved, the number and size of the metastasis, the location, the symptoms related to the primary in the colon or rectum, whether the tumor is resectable or not, and the patient's performance status. Treatment decisions should be made after discussion in a multidisciplinary tumor board.²⁹⁷ A simplified algorithm for the treatment of patients with stage IV CRC is presented in Algorithm 68-3. The discussion is centered on patients with liver metastasis, but these principles are equally applicable to patients with lung metastasis. Surgery is the only curative treatment for patients with colorectal metastasis. Other forms of local therapy, such as ablation, may improve survival. Most patients with metastatic disease benefit from systemic chemotherapy, either as adjuvant treatment to surgery or as the sole form of treatment.

Table 68-10 Comparison of Surveillance Options After Curative Resection^a

	History and Physical	CEA	Colonoscopy	Imaging	Additional Notes
US Multi-Society Task Force (2006) ²²	q3–6 months for first 2–3 years	—	At 1 year, if normal then next in 3 years, if normal then next in 5 years	—	When complete perioperative colonic evaluation not performed (e.g. obstructing cancer), intraoperative colonoscopy or at 3–6 months post-op
NCCN (2013) ²³	q3–6 months (years 1, 2); q6 months (years 3–5)	q3–6 months (years 1, 2); q6 months (years 3–5)	At 1 year, if normal then next in 3 years, then q5	CT q1 year (3 years)	If preoperative colonoscopy not performed, should be done at 3–6 months post-op
ESMO (2010) ²⁴	q3–6 months (years 1–3), q6–12 months (years 4, 5)	q3–6 months (years 1–3), q6–12 months (years 4, 5)	At 1 year, then q3–5 years	CT C/A q6–12 months (3 years); CEUS can substitute for CT Abd	Contrast-enhanced U/S can substitute for CT abdomen
NICE (2014) ²⁵	—	At least q6 months (3 years)	At 1 year, then q5 years	CT C/A/P twice in first 3 years	
ASCO (2013) ²⁶	q3–6 months (5 years)	q3–6 months (5 years)	At 1 year, then q5 years	CT C/A/P q1 year (3 years)	If preoperative colonoscopy not performed, should be done after adjuvant therapy (before 1 year)
JSCCR (2010) ²⁷	q3 months (years 1–3), q6 months (years 4, 5)	q3 months (years 1–3), q6 months (years 4, 5)	At 1 year, then at 3 years	CT C/A q5 months (years 1–3), then q1 year (years 4, 5)	

*Summary estimation of published guidelines. Please refer to primary sources cited for more specific algorithms and details. Reinvestigation and complete staging is recommended for any signs suspicious for recurrence.

Algorithm 68-3. Stage IV rectal cancer treatment algorithm.

Treatment of the Primary Tumor in Stage IV CRC

In the past, all patients presenting with synchronous metastasis were recommended to have resection of the primary tumor, to avoid complications such as obstruction or perforation during treatment of the metastatic disease. However, recent data suggest that patients with unresectable metastasis and an asymptomatic primary are unlikely to develop complications related to the primary tumor that require surgical intervention while the patient is receiving systemic chemotherapy. Currently, primary tumor resection is recommended for patients undergoing curative-intent resection of all metastatic disease, or for patients with unresectable metastasis and a symptomatic primary tumor. The treatment of patients

with asymptomatic primary tumor and unresectable metastasis is controversial. The benefit of avoiding complications related to tumor progression should be balanced against the mortality and morbidity associated with a noncurative resection, and the delay in starting systemic chemotherapy.

Observational studies and secondary analysis of prospective trials have reported an association between primary tumor resection and improved survival. A recent meta-analysis found a difference of 6.4 months in survival in patients undergoing resection.²⁹⁸ However, these studies are limited by strong patient selection bias and outdated chemotherapy regimens. Patients undergoing resection are more likely to have liver-only disease, single metastasis, and tumors located in the colon. Rectal cancer patients are less likely to undergo primary tumor resection compared to patients with colon cancer, probably due to the higher complexity of rectal surgery, the possibility of using palliative CRT, and the fear of a colostomy.

Resection of asymptomatic tumors in stage IV disease has not consistently shown improvements in survival, nor does it necessarily reduce the risk of complications.²⁹⁹ A recent analysis of the SEER database revealed that the proportion of patients with stage IV CRC undergoing primary tumor resection has been progressively decreasing in the last decade.³⁰⁰ Despite this decrease in primary tumor resection, relative survival has been increasing during the same period of time. The improvement in survival has coincided with the introduction of more effective chemotherapy agents. However, the relative contribution of the declining rate of primary resection and the more active chemotherapeutic agents is unknown. These data lend support to current guidelines that do not recommend primary tumor resection in asymptomatic patients with unresectable metastasis.^{177,301} In the SEER data analysis, more than half of the patients with stage IV CRC, diagnosed in 2009, had resection of the primary tumor, suggesting that current treatment practice lags behind evidence-based treatment guidelines.

Surgical Treatment of Colorectal Metastasis

Overall, only 6% of CRC patients with liver metastasis survive beyond 5 years, but in patients with resectable liver metastasis the reported 5-year survival rate ranges from 25% to 40%. Patients with a single, isolated liver metastasis have 5-year overall survival rates as high as 71%. Liver metastases are considered resectable with curative intent if all disease can be removed, with negative resection margin, while preserving adequate liver reserve. Incomplete resection or tumor debulking is not recommended, because it is associated with morbidity without impacting survival. The size of the metastasis is not a contraindication for surgery. When a curative liver resection may potentially result in insufficient liver remnant, portal vein embolization of the involved liver lobe is recommended to induce hypertrophy of the contralateral lobe of the liver. Repeated resection of recurrent liver metastasis is feasible, but the probability of survival decreases with each subsequent resection.

The role of nonsurgical liver-directed therapy for the treatment of liver-only or liver-dominant metastatic disease is controversial. Tumor ablation is indicated in patients who are amenable to local therapy, but are not candidates for surgical resection due to comorbidities. It can also be combined with surgery in patients with mixed resectable and unresectable lesions due to their anatomical location or insufficient liver remnant.³⁰² Other liver-directed therapies for which there is no consensus regarding efficacy are liver-directed chemotherapy using a hepatic artery infusion pump, transarterial hepatic chemoembolization/radioembolization, and liver-directed radiation.

Colorectal lung metastasis can also be surgically removed following the same principles outlined for liver metastasis. Resection must be complete, based on the anatomic location of the disease, and with maintenance of adequate respiratory function. Resection of both liver and lung metastasis is feasible in selected cases, but resection in the presence of nonhepatic extra-pulmonary disease should be reserved for carefully selected patients. Ablation and radiation are also options for patients with nonresectable lung metastasis.³⁰¹

Chemotherapy for Metastatic Disease

Principles of Chemotherapy

6 A number of antineoplastic agents such as 5-FU or capecitabine, oxaliplatin, and irinotecan, and new biologic agents, such as bevacizumab, ziv-aflibercept, cetuximab, panitumumab, and regorafenib, are currently used in combination or as single agents in patients with metastatic CRC. The putative mechanism of action and the toxicity profile of each drug are presented in [Table 68-11](#). The choice of the treatment regimen is based on the goals of therapy, the type and time of previous therapy, and the toxicity profile of the constituent drugs.^{177,301} The chemotherapy regimens commonly used as first-line therapy in patients appropriate for intensive therapy include: FOLFOX (5-FU/LV/oxaliplatin), FOLFIRI

(5-FU/LV/irinotecan), CapeOx (capecitabine/oxaliplatin), infusional 5-FU/LV, capecitabine as a single agent, or FOLFIRINOX (5-FU/LV/oxaliplatin/irinotecan). Cetuximab or bevacizumab can be added to first-line therapy in patients with KRAS/NRAS wild-type CRC, and other combinations such as FOLFOXIRI with bevacizumab have shown promising results.^{303,304} The role of maintenance therapy after first-line therapy, and treatment after progression of metastatic disease on first-line therapy, is beyond the scope of this chapter. Median survival of patients with unresectable metastatic CRC, which previously rarely exceeded 12 months, now exceeds 30 months when these agents are used. Increasing evidence suggests that the selection of chemotherapeutic agents will continue to be guided by molecular and genomic characterizations. Early reports have indicated that combined therapy with BRAF and EGFR inhibitors may be effective in treating BRAF V600E metastatic CRCs specifically.³⁰⁵

Adjuvant Chemotherapy in Resectable Disease

The majority of patients who undergo resection for CRC liver metastasis ultimately relapse in the liver. It is theorized that the addition of systemic therapy provides treatment of occult micrometastatic disease, reducing the risk of relapse. A number of randomized controlled trials have found a modest improvement in RFS, but not in OS, with chemotherapy delivered before or after liver resection, compared with resection alone. The optimal timing of chemotherapy remains unknown.³⁰⁶ The potential advantages of preoperative therapy include earlier treatment of micrometastatic disease, evaluation of tumor responsiveness, and the possibility of avoiding resection in patients with tumor progression during therapy. The main disadvantages of preoperative chemotherapy are the progression of nonresponsive tumors that become unresectable during systemic chemotherapy, and the increase in perioperative morbidity due to chemotherapy-induced liver toxicity. The EORTC Intergroup Trial – the only randomized trial evaluating the role of perioperative FOLFOX (3 months before and 3 months after liver surgery) in the management of resectable liver metastases – demonstrated an absolute increase of 7.3% in 3-year progression-free survival in the combined treatment group, compared with the resection-alone group.^{307,308} This trial demonstrated an increased rate of postoperative complications in the chemotherapy group (25%) compared with surgery-alone (16%), specifically showing a doubling in biliary fistula and hepatic failure rates. The study concluded that perioperative chemotherapy may improve cancer-specific outcomes, but at the cost of increased rates of postoperative complications, including liver dysfunction. Long-term follow-up has revealed the same benefit in progression-free survival, but no difference in OS with the addition of perioperative chemotherapy. The chemotherapy regimens used in the adjuvant setting are the same as those used in first-line therapy. However, bevacizumab can be added as long as it is discontinued at least 6 to 8 weeks before surgery and not restarted for 8 weeks after surgery, because it interferes with wound healing.³⁰⁹ Cetuximab and panitumumab have been added to first-line regimens in patients with KRAS/NRAS wild type, but the benefits have been inconsistent. In fact, recent data suggest these could even be detrimental; therefore, they are not recommended at this time.³¹⁰

Table 68-11 Main Chemotherapeutic Agents

Agents	Mechanism	Common Side Effects
5-FU	Pyrimidine analog, thymidylate synthase (TS) inhibitor	Hematologic: thrombocytopenia. GI: mucositis. Hepatic steatosis (yellow liver). Photosensitivity
Folinic acid (leucovorin)	Enhances 5-FU effects and contributes to TS inhibition	—
Irinotecan	Topoisomerase I inhibitor	Hematologic: myelosuppression. GI: diarrhea. Hepatic steatosis.
Capecitabine	Pro-drug of 5-FU	GI: mucositis
Oxaliplatin	Platinum-based agent, DNA cross-linking	Peripheral neuropathy GI: sinusoidal congestion (blue liver)
Cetuximab/panitumumab	Anti-EGFR monoclonal antibody (for use with KRAS wild-type tumors only)	Acneiform skin rash
Bevacizumab	Anti-VEGF monoclonal antibody	Compromised wound healing

Chemotherapy in Borderline Resectable Disease

A few patients present with liver-only metastases that are not amenable to a complete resection, due to close proximity to essential anatomical structures. Systemic chemotherapy in this setting aims to

convert an unresectable patient to resectable status. The duration of treatment in these patients is important. There is a need to balance the minimum time required to achieve a response that will make the patient resectable, while avoiding hepatotoxicity from the chemotherapeutic agents. Both FOLFOX and FOLFIRI increase resectability in 12.5% to 40% of patients initially considered unresectable. A study has shown that adding irinotecan to FOLFOX (FOLFIRINOX) in patients with initially unresectable metastasis increased the resection rate compared to FOLFOX alone.³¹¹ Adding EGFR inhibitors to FOLFOX or FOLFIRI increased the resectability rate in patients with wild-type KRAS/NRAS tumors and initially unresectable liver metastasis.^{312,313} Angiogenesis inhibitors combined with FOLFIRI modestly increase resectability of initially unresectable liver metastasis compared to FOLFIRI alone, but have no effect when combined with oxaliplatin-containing regimens.^{314,315} To limit FOLFOX- and FOLFIRI-associated toxicity, patients receiving systemic chemotherapy to increase resectability should be evaluated for response every 2 months, and undergo surgery as soon as they become resectable.

Treatment of Peritoneal Carcinomatosis

Most patients with peritoneal carcinomatosis have widespread metastatic disease, and are treated with systemic chemotherapy. The treatment of patients with the peritoneum as the only site of metastasis is controversial.^{316,317} Complete cytoreductive surgery (CRS), with removal of all visible abdominal and pelvic disease, and hyperthermic intraperitoneal chemotherapy (HIPEC) are now commonly used in patients with peritoneum-only metastatic CRC. The most commonly used drug for intraperitoneal chemotherapy is mitomycin C, which is minimally active against CRC. As experimental data do not support any biologic benefit from the hyperthermia component, the role of HIPEC has been questioned. Oxaliplatin, irinotecan, doxorubicin, paclitaxel, and carboplatin have also been tested. Comparative studies have not shown a conclusive advantage of mitomycin C over oxaliplatin.³¹⁸ This aggressive treatment is associated with significant mortality (0.9% to 5%) and morbidity (12% to 52%), with the most common complications being surgical site infection, hematologic toxicity, and intestinal fistula. Many single institution case series have reported improved survival in patients treated with CRS and HIPEC followed by systemic chemotherapy, compared to systemic chemotherapy alone. A recent review of 19 studies conducted from 1999 to 2009 reported a median survival of 33 months for patients treated with CRS and HIPEC versus 12.5 months for patients undergoing palliative surgery and/or systemic chemotherapy.³¹⁹ These studies have been criticized because of strong patient selection bias favoring peritoneum-only disease in the CRS/HIPEC group, an undefined role for palliative treatment, and suboptimal chemotherapy in the nonsurgical group. The only prospective trial published so far randomized patients to 5-FU/LV with palliative surgery versus CRS, HIPEC, and postoperative 5-FU/LV. OS was 12.6 months in the standard arm versus 22.2 months in the HIPEC group.³²⁰ This study has been criticized because it also included patients with pseudomyxoma peritonei of appendiceal origin, and because it was conducted before most of the drugs currently used in metastatic disease were available. In spite of this criticism, CRS and HIPEC are commonly performed regimens for patients with peritoneum-only colorectal metastasis.³²¹

The selection criteria for this complex and potentially morbid treatment are not well defined. The most important prognostic factors in patients undergoing CRS and HIPEC are the Peritoneal Cancer Index (PCI), a grading of tumor burden at the time of surgery, and the completeness of cytoreduction (CC) score. Unfortunately, the determinants of these scores are only available at the time of abdominal exploration during surgery. Therefore, they have not been useful in selecting those patients more likely to benefit from CRS and HIPEC. Recently, a Peritoneal Surface Disease Severity Score (PSDSS) that includes patient symptoms, extent of peritoneal dissemination, and primary tumor histology has been developed to stratify patients at the time of diagnosis, without the need of an operation.³²² The PSDSS score system has been found to be an independent prognostic factor in multivariate analysis, not only for patients undergoing CRS and HIPEC, but also for patients treated with systemic chemotherapy. This score may help eliminate selection bias in future comparisons of different treatments, in patients with peritoneum-only metastatic CRC.

TREATMENT OF LOCALLY RECURRENT CRC

LR after curative-intent surgery is defined as a relapse of tumor in the surgical field of the initial procedure, including the anastomosis, regional nodes, surgical scars, and drain tracts.³²³ While most patients with LR also have distant metastasis, a few have isolated LR. A complete surgical resection is the only curative option for patients with isolated locally recurrent CRC, but is associated with

considerable morbidity and mortality.³²⁴ In spite of this criticism, CRS plus HIPEC is commonly performed for patients with peritoneum-only colorectal metastasis.

The risk of LR is higher for rectal cancer compared to colon cancer, for advanced stage tumors (T4), for tumors with high-risk histologic features (lymphovascular and perineural invasion, grade III or IV, signet ring cell histology), perforating or obstructing tumors, and patients with close or involved CRM. Most local recurrences present within 3 years after the primary surgery, but LR tends to occur later in patients treated with CRT and surgery, compared to those treated with surgery alone. In the Dutch TME trial, 10% of LRs occurred more than 3 years after surgery in patients treated with TME, versus 31% in patients treated with preoperative RT and TME.³²⁵

While some LRs are detected through surveillance, while asymptomatic, most are diagnosed after they become symptomatic. Symptoms of local recurrence include bowel obstruction, abdominal distension, rectal or vaginal bleeding, and urinary problems.³²⁶ Pelvic pain is common, and is a predictor of reduced long-term survival.³²⁷ A common manifestation in patients who have had abdominoperineal resection (APR) is a nonhealing perineal wound. Whenever symptoms suggestive of recurrence arise, a detailed history and complete physical examination must be done. This includes DRE in patients who have undergone sphincter-preserving surgery, and a pelvic examination in females. If recurrent tumor is identified, endoscopy and imaging studies will help assess extent of disease and surgical risk. A complete colonoscopy should be performed if possible. Intraluminal recurrences are easily diagnosed with endoscopy and biopsy. Cystoscopy is required for patients who present with urogenital symptoms, as these strongly indicate tumoral invasion of the ureters and bladder.³²⁸ CEA is routinely measured during follow-up surveillance after primary rectal cancer resection. Elevation of this tumor marker is frequently the first sign of recurrence³²⁹; however, elevated CEA is present in only about 50% of patients. Patients with elevated CEA should undergo further work-up with imaging studies.

A CT scan of the chest, abdomen, and pelvis is the primary imaging modality used in these patients, and it is especially helpful in identifying metastases in the liver, lung, and peritoneum, and evaluating regional adenopathy.³³⁰ MRI is more accurate than CT in detecting and staging pelvic LR³³¹; although it has been ineffective when added to routine follow-up in detecting ERUS it may be useful in diagnosing LR after LE of distal rectal cancer.³³² Positron emission tomography (PET) using the glucose analog fluorodeoxyglucose (FDG), particularly when combined with a CT scan, is helpful in distinguishing between postsurgical changes and tumor recurrence. In a recent meta-analysis comparing FDG-PET, FDG-PET/CT, CT, and MRI in the detection of recurrent CRC in patients with high suspicion of recurrent disease, based on symptoms or elevated CEA, FDG-PET and FDG-PET/CT performed more accurately than CT scan.³³³ PET/CT also demonstrated greater accuracy than MRI in identification of lymph node recurrence in a lesion levels analysis.³³⁴ Overall accuracy of FDG-PET/CT is slightly higher than FDG-PET: 92.3% (94% sensitivity, 77.2% specificity) versus 89% (90.3% sensitivity, 80% specificity).³³⁵ However, lesions measuring less than 1 cm in diameter are more difficult to detect with PET scanning, as are mucinous tumors, due to poor FDG uptake. Finally, FDG-PET cannot be used to detect or evaluate LR if there is residual inflammation of the tumor bed secondary to chronic leaks. Regardless of the imaging studies used to help diagnose LR, histologic confirmation is imperative. Anastomotic recurrences should be biopsied endoscopically; extraluminal recurrences can usually be biopsied percutaneously, under radiologic (CT) guidance.

7 The treatment of locally recurrent CRC should be discussed in a multidisciplinary setting, since it often involves colorectal surgical oncologists, radiation oncologists, medical oncologists, and other specialists. Patients with multifocal LR should be treated with systemic chemotherapy, as in metastatic disease. Only patients with localized LR and good performance status are candidates for surgical resection. Even these patients may benefit from additional systemic chemotherapy or chemoradiation, if they did not receive it at the time of treatment of the primary tumor.³³⁶ Some patients with recurrent rectal cancer treated initially with standard doses of radiation (50.4 Gy in 180 cGy fractions, or biologically equivalent total dose), can be re-irradiated to the gross tumor volume using small fractions (180 to 200 cGy), with or without sensitizing chemotherapy.³³⁶ Re-irradiation seems to increase the possibility of an R0 resection in patients with resectable disease, or provides good palliation in unresectable patients. Following preoperative chemotherapy and/or radiotherapy, re-staging should be done to exclude interim development of distant metastasis and to ascertain the extent of the LR.

Surgery is the only curative option for patients with locally recurrent rectal cancer. Without treatment, median survival is typically 6 to 7 months³³⁷; systemic chemotherapy can prolong survival, similar to patients with systemic recurrence. Only patients with good performance status, with recurrences that, based on anatomical location, are amenable to an R0 resection, should be considered

surgical candidates. A resection with gross positive margins (R2) should not be attempted, because it provides no oncologic advantage to the patient and is associated with significant morbidity. Patients found to have microscopic positive margins (R1) may benefit from intraoperative radiation. However, this modality is only available at some institutions, and requires preoperative planning. Therefore, the treatment of locally recurrent CRC should be limited to institutions with appropriate expertise and equipment.

Only about one-third of patients with isolated locally recurrent CRC are candidates for surgical salvage with curative intent. In the Intergroup Study 0114, which investigated several chemotherapy regimens in patients with locally advanced rectal cancer, only 159 (35%) of the 448 patients with single-site first recurrences in the liver, lung, or pelvis had curative-intent surgery.³²⁶ The proportion of patients undergoing resection was similar for liver, lung, or local recurrences. OS differed significantly between the resected and nonresected groups, with 5-year OS of 27% and 6%, respectively ($p < 0.001$). The 5-year DFS was in the range of 30% for patients undergoing resection of tumors in solitary sites of the liver or lung, and 20% for those undergoing resection of LR. Retrospective case series from institutions with experience in the treatment of locally recurrent CRC report 5-year survival rates close to 35% for patients with R0 resections, compared to 21% for patients with R1 resections.

Palliation is an important aspect of the treatment of patients with unresectable LR. Bowel obstruction often requires palliative surgery, stomas, endoluminal stents, or percutaneous gastrostomy tubes. Urinary obstruction is common, requiring stents or percutaneous nephrostomies. Pain is a common symptom in these patients, often requiring the assistance of pain specialists and specialists in palliative care.

Chapter 69

Diverticular Disease

Lauren A. Kosinski, Kirk Ludwig, and Mary F. Otterson

Key Points

- 1 Diverticulosis and its complications are common in Western societies.
 - 2 Sigmoid and left colon involvement predominate in non-Asian industrialized nations; the rectum is spared.
 - 3 Lack of dietary fiber, colonic anatomy, and disordered colonic motility are likely contributors to the development of diverticulosis.
 - 4 New data suggest that uncomplicated diverticulitis may be an inflammatory rather than an infectious process.
 - 5 Computed tomography (CT) imaging markedly improves diagnostic accuracy and treatment planning.
 - 6 Early, judicious use of contrast enema studies or colonoscopy can safely help distinguish diverticular stricture from cancer.
 - 7 Antibiotic therapy, bowel rest, and percutaneous drainage of diverticular abscesses can often convert surgical emergencies into elective operations.
 - 8 Bowel resection with primary anastomosis and temporary, diverting loop stoma is favored in acute cases when possible; single-stage operations are preferred for elective cases.
 - 9 Early enthusiasm for emergency laparoscopic washout and repair of diverticular perforations has not been supported by prospective, randomized trials.
 - 10 Criteria for elective colon resection for diverticulitis are evolving and trending toward more restrictive indications.
-

Diverticular disease (DD) is one of the most common problems treated by surgeons, and management strategies have evolved significantly in the last 15 years. A short time ago, virtually all cases of acute diverticulitis were treated as surgical emergencies. Patients routinely underwent staged procedures and were taken to the operating room for sigmoid colectomy and temporary end-colostomy within hours of admission. Surgical and radiologic innovations have introduced less invasive options for managing even complex disease. Surgery, when necessary, is often performed electively or semi-electively.

Key among recent major shifts in the diagnosis and management of DD are (a) strategies for converting diverticular surgical emergencies into single-stage, elective operations with avoidance of a colostomy; (b) utilization of computed tomography (CT) imaging for diagnosis and CT-guided percutaneous drainage of diverticular abscesses; (c) reconsideration of indications for elective surgery; and (d) emergence of laparoscopic surgical techniques as state-of-the-art approaches for DD. Fear that younger patients with diverticulitis or older patients with a single episode of diverticulitis were at increased risk of perforated diverticulitis and colostomy construction has been allayed by data that show no increased risk. These data and recognition that even elective resection for DD may have higher complication and colostomy rates than elective colon cancer resections¹ have fueled concern that the cure might be worse than the disease and are shaping more stringent guidelines for elective resection.

CLASSIFICATION

1 Diverticulosis refers to the presence, whether symptomatic or asymptomatic, of colonic diverticula. In common medical usage, this refers to the presence of pseudodiverticula in which mucosa and submucosa have herniated through the circular layer of the muscularis propria, a very common acquired condition in Western societies. True diverticula are rare. DD refers to the broad range of symptoms and findings associated with diverticulosis and includes diverticulitis, an inflammatory and often infectious process.

Inflammation can be acute or chronic. Acute inflammation can present with a pericolonic phlegmon, colon perforation leading to focal abscess formation, or generalized purulent or fecal peritonitis. Acute and chronic inflammation can result in fistula formation between the involved bowel segment and the bladder, vagina, or skin. With chronic or recurrent inflammation, scarring of the involved segment can cause bowel wall thickening, dysmotility, and stricture, which may present as altered bowel habit or even frank obstruction.

ANATOMY

2 Colonic diverticula are pulsion diverticula that occur in predictable sites on the bowel wall. Likewise, the pattern of segmental involvement of the colon and its progression are predictable. The sigmoid colon is at highest risk and is affected in 95% of patients. Involvement is isolated to the sigmoid colon in 30% to 60% of cases. Total colonic involvement occurs in 7% to 10% of cases.² The rectum is almost always spared. This segmental pattern of involvement is not observed in Asia, where 70% of pseudodiverticula are isolated to the right colon and cecum. The reason for this discrepancy is not known. Right colon pseudodiverticula are more likely to be solitary and tend to originate near the ileocecal valve.^{3,4} When true colonic diverticula develop, they are also more likely to be right sided; however, they are still much less common than pseudodiverticula of the right colon.

INCIDENCE

Diverticulosis is rare in nonindustrialized, less affluent societies. The French surgeon Alexis Littre is credited with first describing diverticulosis in 1700, but it was not until the mid-1800s that there were reports in the medical literature about the disease process and its treatment.⁵ The prevalence of diverticulosis increased after the industrial revolution and through this century. Even before 1940, it was recognized infrequently; retrospective reviews of colon radiographs and pathologic specimens record an incidence of 5% to 10%.⁶ An incidence of 46% in people 51 years of age and older was reported by Hughes from postmortem studies in 200 cadavers (Table 69-1).⁷ Incidence as a function of gender varies by study, some studies citing an increased incidence among men and others finding a higher incidence among women. It may be that the spectrum of complications and the age at which they develop are gender specific. The majority of people with diverticulosis remain asymptomatic; only 15% to 30% will go on to develop symptomatic disease.⁸ Of these, only 30% will require operative treatment.⁹ In the United States in 1998, 2.2 million cases of DD were treated at an estimated cost of \$2 billion.¹⁰ In 2005, DD was the primary diagnosis in 307,000 hospital discharges and accounted for 1.6 million inpatient days of care.¹¹

Table 69-1 Incidence of Diverticulosis in Western Society

Age	≤25 Yrs	≤45 Yrs	>60 Yrs	>80 Yrs
Incidence	1–2%	33%	40%	60%

ETIOLOGY

3 Neither the etiology of diverticulosis nor factors causing progression to symptomatic disease have been rigorously defined, but lack of dietary fiber, colonic dysmotility, and colonic structural abnormalities and age-related changes have all been implicated. There may be an association between irritable bowel syndrome (IBS) and diverticulitis, the microbiome may be a mediator in diverticular inflammation, and idiopathic inflammation may also contribute to the DD spectrum.

Structural/Anatomic Factors

In the colon, the outer, longitudinal layer of the muscularis propria is condensed in three longitudinal bands called the taeniae coli. One of these runs along the mesenteric aspect of the colon; the other two are antimesenteric in location (Fig. 69-1). Mesenteric blood vessels encircle the colon and penetrate the circular muscle in the intertaenial areas between the mesenteric taenia and the two antimesenteric taeniae. Pseudodiverticula develop at areas where these vessels pass through muscle.¹² Postmortem

studies of the colon wall showed thinning of the circular muscle associated with early diverticula. Gaps in the circular muscle were observed with larger diverticula.⁷

Figure 69-1. Cross section of the colon illustrating the relation of diverticula to the blood vessels penetrating the circular muscle layer, the taeniae, and the appendices epiploicae.

Figure 69-2. Postevacuation film of barium enema, demonstrating a giant colonic diverticulum (*arrows*) partially filled with barium. (Reproduced with permission from McNutt R, Schmitt D, Schulte W. Giant colonic diverticula. *Dis Colon* 1988;31:625.)

In contrast to typical pseudodiverticula, giant colonic diverticula almost always arise from the antimesenteric border of the colon. They are assumed to be a complication of ordinary colonic diverticulosis, possibly developing after inflammatory narrowing of the neck of a pseudodiverticulum causes a ball-valve mechanism that entraps gas in the diverticulum, causing it to enlarge (Fig. 69-2).¹³

The observation of colonic diverticula in young patients with connective tissue disorders such as Marfan disease and Ehlers–Danlos syndrome raises the question of whether connective tissue genetic derangements play a role in diverticulosis development.^{14,15} Ordinary senescent connective tissue change may be a factor as well. Cross-linkage of collagen fibrils in the colon wall increases with age, rising markedly after age 40, and appears to decrease compliance of the colon wall. In comparison with age-matched controls, this cross-linkage is exaggerated in patients with diverticulosis.¹⁶

Thickening of the colon wall in diverticulosis was originally attributed to muscle hypertrophy.^{12,17} This was disproven by histologic studies, but increased elastin deposition in the taeniae coli of patients with uncomplicated diverticulosis has been shown. The taeniae are shortened as a result, causing the circular muscle to be accorded in the two intertaenial zones, the same areas where pseudodiverticula more commonly form.¹⁸ The functional significance of this is not known, but it has been speculated that muscle contractions may be stronger in these areas.

Motility Factors

Four unusual colonic motility patterns have been observed in the setting of diverticulosis: segmentation, high-pressure waves, slow-wave motility pattern, and disorganized propulsive activity.

Segmentation

Painter et al.¹⁹ used cineradiography and manometry to study colonic motility and reported that when simultaneous haustral contractions occur in the same segment of colon, high pressure is generated in the intervening bowel, causing ballooning of the colon wall and distention of diverticula (Fig. 69-3).

Figure 69-3. The role of segmentation in colonic physiology. **A:** Interhastral ring contraction (“segmentation”) leads to increased luminal pressure when there is simultaneous segment wall contraction. **B:** Relaxation of an interhastral ring allows passage of colon contents from the high-pressure segment to a neighboring low-pressure segment. **C:** Resistance to colon content flow can be imposed by interhastral ring contraction that functions as a baffle. Resultant interruption of flow can also significantly increase luminal pressure in that segment. **D:** Diverticula always arise from the segment wall between interhastral rings and never at the rings.

High-Pressure Waves

High-pressure waves are independent of normal peristalsis and have an amplitude of 10 mm Hg in normal patients but have higher amplitude (up to 90 mm Hg) and longer duration in patients with diverticulosis.²⁰

Slow-Wave Motility Pattern

The normal slow-wave pattern in the colon is altered in DD.^{21,22}

Disorganized Propulsive Activity

High-amplitude propulsive contractions occurred more frequently and were more likely to be disorganized in patients with DD than normal subjects. Retropulsive contractions occurred more frequently in segments of colon with diverticulosis.²³

Diet

Decreased dietary fiber is the most consistent factor associated with the high incidence of diverticulosis in Western populations. Painter and Burkitt first elucidated this connection after noting the striking disparity in incidence between British society and sub-Saharan populations. They measured colon transit time and stool weights in over 1,000 individuals in the United Kingdom and sub-Saharan Africa. The rise in the incidence of DD coincident with the rise in refined food products in diets in the West was also noted.²⁴ Painter and Burkitt²⁵ also reported improvement of DD symptoms in patients who increased dietary fiber and recrudescence of symptoms once fiber intake decreased again. There is now a rising

incidence of diverticulosis among previously low-risk populations in concert with changes to a Western-style diet as a consequence of economic development or immigration. Japanese immigrants to the United States acquire diverticulosis risk comparable to other Westerners, although the right-sided predominance of diverticulosis seen among Asians persists.^{5,26} The exact protective mechanism of stool bulk is not understood. Evidence that contradicts the role of low-fiber diet or constipation as contributing factors to DD is provided by a study of 2813 patients enrolled in a vitamin D and colon polyp colonoscopy study. Five hundred and thirty-nine patients aged 45 to 75 who had the incidental colonoscopic finding of diverticulosis without antecedent history of it were compared to 1569 controls. The control group had a higher self-reported history of less frequent or lumpy stools, and there was no difference in dietary fiber intake. However, inaccuracies of bowel and diet habit self-reports, the evaluation of individuals with asymptomatic diverticulosis versus symptomatic DD, and the imperfect sensitivity of colonoscopy for detection of diverticulosis should be considered in the interpretation of these findings.²⁷

While the focus on dietary fiber has emphasized insoluble fiber, soluble fiber may also be of value. Soluble fiber is processed by intestinal flora, which may in turn affect diverticulosis.^{26,28} Finally, despite the long-held admonition to avoid eating nuts and seeds, there is no evidence to support this recommendation.²⁹

Other Factors

Other neurologic and chemical mediators of colonic motility may play a role in pseudodiverticula genesis. Vasoactive intestinal peptide levels are increased in the bowel wall of patients with diverticulosis.³⁰ Age-related vagal attrition has been postulated to contribute to colonic smooth muscle dysmotility.³¹ Alterations of serotonin expression and function are noted after resolution of acute diverticulitis and may contribute to lasting symptoms.³²

Emerging Concepts

Two observations have focused interest in the possibility of a primary inflammatory etiology of diverticulitis. One is that a subset of patients with uncomplicated diverticulitis are unresponsive to antibiotic therapy as would be expected in the case of a smoldering, focal bowel-wall infection due to diverticular sepsis or microperforation (see below). The other is that anti-inflammatory medications appear to reduce flares of diverticulitis in some patients. Shifts in the microbiome have also been detected in other lower gastrointestinal system disorders including colon cancer and IBD.^{33–36} Subtle peridiverticular inflammatory changes have been noted in some patients with asymptomatic DD.³⁷ Whether diverticulosis results from or causes inflammation and whether progression to diverticulitis likewise results from or causes inflammation is an open question. Similar questions have existed regarding an interrelation between IBS and DD. A longitudinal study of administrative and clinical data from the Veterans' Association found the hazard ratio for developing IBS after an episode of diverticulitis was 4.7 compared to controls even though the study group of older males (mean age 62 years) is generally a lower risk group for IBS.³⁸ Whether these “new IBS” cases should actually be regarded as segmental diverticulitis that could be managed by resection as opposed to a pan-colonic phenomenon has not been demonstrated.

Pathogenesis of Diverticulitis

4 The process by which a subset of people with diverticulosis develop diverticulitis has yet to be explained. Overwhelming inflammatory changes that develop with perforation or other complications of diverticulitis likely obscure subtle histologic details that might explain the pathogenesis of the disease. Traditionally, it has been postulated that mechanical obstruction by food or fecal material of a diverticulum leads to bacterial proliferation, gas, and toxin production in the occluded diverticulum, causing diverticulitis. However, the largely extracolonic manifestations of diverticulitis (phlegmon, abscess, and free perforation) suggest micro- or macroperforation as the inciting event, possibly as a kind of diverticular “blow-out” secondary to segmentation-type contractions or high-pressure waves. In recent years (and perhaps with the rising number of patients undergoing screening colonoscopy), peridiverticular inflammation has been identified, often in asymptomatic patients. Diverticulitis-associated colitis is of unrecognized clinical significance, partly because so many patients with these findings are asymptomatic and partly because the findings are not uniformly evident in patients requiring surgical therapy for diverticulitis. It has been suggested that low-grade inflammation could alter bowel motility and thereby contribute to diverticular perforation risk. Endoscopists are cautioned

to avoid confusing diverticulitis-associated colitis with inflammatory bowel disease. Probiotics and nonsteroidal anti-inflammatory medications are being explored as potentially protective agents.^{26,39,40}

Diagnosis

Noninflammatory Diverticular Disease

Most patients with diverticulosis noted on barium study, colonoscopy, or abdominal CT scan are asymptomatic. In patients who have vague, crampy, left lower quadrant pain in the absence of fever, leukocytosis, or CT findings of focal inflammation, other causes of pain must also be considered. Additional symptoms reported may include nausea, flatulence, bloating, and change of bowel habit. The differential diagnosis includes colonic adenocarcinoma, constipation, inflammatory bowel disease, and IBS. There are no peritoneal signs on examination, the rectal examination is unrevealing, and proctoscopy shows no inflammation. Postinflammatory neurogenic alteration has been postulated as a cause of visceral hypersensitivity.^{41–43} Nonspecific, mild mucosal inflammation and muscle spasm may also contribute. There is considerable overlap with IBS. In addition to high-fiber modification of the diet and bulk-forming agents such as psyllium or flaxseed, anticholinergics, analgesics, and antibiotics can be prescribed to manage symptoms.

Hemorrhagic Diverticular Disease. Like bleeding from colonic angiodysplasia, diverticular hemorrhage is classically asymptomatic until presentation with lower gastrointestinal hemorrhage that can be massive. This differs from hemorrhage from inflammatory bowel disease or ischemic colitis where there are typically symptoms before bleeding begins. A foregut source of bleeding must be excluded by nasoenteric recovery of bilious, nonbloody aspirate or upper endoscopy. Likewise, an anorectal source of bleeding must be excluded by examination. Localization of lower gastrointestinal hemorrhage of any cause is necessary to help guide appropriate colon resection should that be required. Although most cases of diverticular hemorrhage are self-limited, recurrence or failure of bleeding to stop spontaneously determines the need for resection. Colonoscopy, tagged red blood cell scan, or, if bleeding is brisk enough, angiography is used to localize bleeding (Fig. 69-4).

Giant Colonic Diverticula. Symptoms and signs of giant colonic diverticula may be noninflammatory (pain, bloating, nausea, vomiting, diarrhea, abdominal tenderness and mass) or inflammatory, resulting from perforation (pain, leukocytosis, fever, localized or generalized peritonitis).¹³

Inflammatory Diverticular Disease

The constellation of inflammatory signs and symptoms corresponds to the spectrum of inflammatory complications of DD. The Hinchey classification⁴⁴ categorized the severity of acute diverticulitis and has been modified to reflect refinements of diagnosis enabled by improved CT scan quality (Table 69-2).⁴⁵ The modified classification also includes manifestations of chronic inflammation such as fistula formation and stricture/obstruction.

Symptoms of acute diverticulitis include steady, left lower-quadrant abdominal pain; fever; change in bowel habits (constipation or diarrhea); anorexia; nausea; vomiting; bloating; and urinary tract symptoms such as urinary frequency or retention. Examination will reveal left lower-quadrant tenderness that may be appreciable only with deep palpation in stage 0 inflammation. In stage I or II inflammation, focal peritoneal signs in the left lower quadrant are likely, and there may be a tender mass. Digital rectal examination may also reveal pelvic tenderness or a tender mass in the cul-de-sac. Generalized peritoneal signs would be expected for stage III or IV inflammation. Dehydration with earlier stages or evolving sepsis with later stages may cause tachycardia and hypotension. Leukocytosis is more likely with advancing stage of inflammation. The differential diagnosis includes perforated colon cancer, acute appendicitis, perforated peptic ulcer, acute ischemic colitis, pancreatitis, and flare of Crohn disease or ulcerative colitis. Normal serum amylase and lipase help exclude a diagnosis of pancreatitis. Imaging studies and endoscopy help to distinguish diverticulitis from the other diagnoses. However, active inflammation or contained perforation may limit the utility of rectal contrast CT, barium enema studies, and endoscopy in the acute setting. Distinguishing perforated colon cancer from DD can be especially challenging, even in the operating room.

Diverticular fistula formation represents internal drainage of an abscess (or external drainage in the case of colocutaneous fistulas). Approximately half of diverticular fistulas are colovesical fistulas. Women with colovesical or colovaginal fistulas have usually had a hysterectomy.^{46,47} Urinary tract infection symptoms, pneumaturia, and fecaluria are common complaints. Recurrent urinary tract

infection in elderly men should raise concern for the presence of a colovesical fistula, which is often secondary to DD. Passage of feces or flatus from the vagina is a characteristic symptom of a colovaginal fistula. Colocutaneous fistulas are a rare complication of DD.

Figure 69-4. Superior mesenteric arteriogram from a patient with bleeding from a right colon diverticulum. **A:** Early radiograph with contrast material outlining the diverticulum (*arrow*). **B:** Late radiograph demonstrating overflow of contrast material into the colonic lumen(*arrow*).

Thirteen percent of large-bowel obstructions are due to DD. The concurrent incidence of colon carcinoma in 7% of patients with symptomatic sigmoid DD confounds diagnosis and treatment.⁴⁸ CT scan is not as reliable for distinguishing these diagnoses as colonoscopy or contrast enema studies.

Right-sided diverticulitis frequently is confused with appendicitis, and misdiagnosis is common. The duration of symptoms is usually longer than appendicitis. Patients are usually older than those with appendicitis (late 30s or 40s) but younger than patients with typical left-sided diverticulosis (over 50 years of age).^{49,50}

CLASSIFICATION

Table 69-2 Modified Hinchey Classification

Hinchey Classification	Modified Hinchey Classification	Comments
	0 Mild clinical diverticulitis	Left lower quadrant pain, elevated white blood cells, fever, no confirmation by imaging or surgery
I Pericolic abscess or phlegmon	Ia Confined pericolic inflammation – phlegmon	
II Pelvic, intra-abdominal, or retroperitoneal abscess	II Pelvic, distant intra-abdominal, or retroperitoneal abscess	
III Generalized purulent peritonitis	III Generalized purulent peritonitis	No open communication with bowel lumen
IV Generalized fecal peritonitis	IV Fecal peritonitis fistula colovesical/colovaginal/coloenteric/colocutaneous	Free perforation, open communication with bowel lumen
Obstruction	Large- and/or small-bowel obstruction	

Figure 69-5. Sigmoid diverticulitis with pericolic abscess(arrows).

Imaging and Diagnostic Studies for Diverticular Disease

Plain Radiographs. While seldom useful in the diagnosis of uncomplicated diverticulitis, a three-way abdominal series that includes an upright chest radiograph, an abdominal flat plate, and a left lateral decubitus view is useful for demonstrating free air. An ileus pattern or soft tissue mass may also be detected.^{51,52}

5 Computed Tomography Scan. CT scanning has revolutionized the diagnosis of acute diverticulitis and, sometimes, by way of percutaneous abscess drainage, its treatment. The accuracy of CT scans in the acute setting is central to the trend toward converting what formerly were surgical emergencies into elective, often single-stage operations. Intravenous and water-soluble oral and rectal enteric contrast should be administered. Water-soluble contrast is used to avoid barium peritonitis that may result if barium leaks from a perforated diverticulum into the peritoneal cavity.

A CT scan can reveal the presence and extent of diverticulosis, but its real strength is characterizing extracolonic inflammatory change. Signs of inflammation include colon wall thickening, pericolic fat stranding, or phlegmon formation. Pericolic abscess size and location can be detected (Fig. 69-5). Perforation is evidenced by free air; contained perforation may be identified by loculated extraluminal pericolic air. CT more accurately demonstrates diverticular abscesses and severity of inflammation than contrast enema studies.⁵³ Air in the bladder or contrast in the vagina may indicate the presence of a fistula (Fig. 69-6).

Figure 69-6. A: Computed tomography scan demonstrating air in the urinary bladder (arrow) in the presence of a colovesical fistula secondary to diverticulitis. B: Air in the urinary bladder (small arrow) in association with a paravesical inflammatory mass (large arrow). (Reproduced with permission from Sarr MG, Fishman EK, Goldman SM. Enterovesical fistula. *Surg Gynecol Obstet*1987;164(1):41–48.)

Rao et al.⁵⁴ reported a misdiagnosis rate of up to 67% for diverticulitis in patients with abdominal pain managed without CT imaging. An alternate diagnosis is suggested by CT scan in 45% to 58% of cases when diverticulitis is not found, including small-bowel obstruction, acute cholecystitis, appendicitis, gynecologic disease, and primary epiploic appendicitis.⁵⁵ Correct preoperative diagnosis of right-sided diverticulitis has also been enhanced by CT scanning.

Not only is CT useful for improving diagnostic accuracy, but also findings can predict failure of medical management or risk of secondary complications following medical management.

Ambrosetti et al. reported on 423 patients with acute diverticulitis on CT scan, categorizing them as having either moderate disease or severe disease. Criteria for moderate disease included localized wall thickening or inflammation of pericolic fat (modified Hinchey stage Ia; see [Table 69-2](#)). Severe disease included the presence of extraluminal air or contrast (contained perforation) or abscess (modified Hinchey stages Ib and II). Of the 42 patients who failed nonoperative management, 32 had severe disease. Twenty percent of those patients who were initially successfully managed nonoperatively developed secondary complications such as fistulas (median follow-up 46 months). They concluded that the presence of severe disease at the index episode predicted failure of nonoperative management and that there is a high risk of secondary complications after initial nonoperative management.⁵⁶

Ultrasound. Abdominal ultrasound has been emphasized in the European literature and is attractive as a strategy for limiting radiation exposure. However, its diagnostic limitations (user dependence, interference from overlying bowel gas, and decreased accuracy in obese patients) have precluded its widespread adoption in the United States. In skilled hands, it may have a role in image-guided percutaneous drainage of abscesses.⁵⁷

Contrast Enema Study (Barium Enema). Contrast enemas have been the “gold standard” test for the presence and anatomic distribution of diverticula ([Fig. 69-7](#)). For reasons cited earlier, CT scan has supplanted contrast enemas in the acute setting. However, they are better than CT for helping distinguish colon cancer from diverticular obstruction, and contrast can also traverse narrowed areas of the colon impassable by an endoscope. While caution must be used in the acute setting to avoid perforation, these studies can be performed safely. Caveats are that contrast must be administered gently, water-soluble contrast should be used, and a single contrast study is performed in unprepared bowel to avoid the increased risk of perforation and fecal contamination with the administration of air. In chronic DD, the contrast enema can demonstrate stricture, angulation, and segmentation-type contractions. It can also be useful for the evaluation of fistulas.

Figure 69-7. Barium enema showing multiple diverticula of the colon.

6 Endoscopy. Like contrast enema studies, colonoscopy or flexible sigmoidoscopy can be used judiciously in the acute setting. It is particularly helpful in distinguishing malignancy from DD and can therefore help guide early management of acute presentations when malignancy as the cause of symptoms is being considered.

Cystoscopy. Cystoscopy can help diagnose colovesical fistulas. Although the fistula tract is usually difficult to see, focal hyperemia and inflammation may be noted. Symptoms of a colovesical fistula and air in the uninstrumented bladder on CT scan are usually sufficient for diagnosis.

TREATMENT

Symptomatic Diverticulosis

Fiber supplements and increased dietary fiber (goal 25 to 30 g/d) constitute the cornerstone of symptomatic diverticulosis treatment once diverticular stricture has been ruled out as the cause of symptoms. Stricture is an indication for elective segmental colectomy, typically a sigmoid colectomy to remove the area of stricture and the most dense region of diverticula.

Hemorrhagic Diverticular Disease

Diverticular hemorrhage stops spontaneously in more than 90% of patients; of these, 75% will not bleed again.⁵⁸ Patients who have a second episode of diverticular hemorrhage should undergo hemicolectomy of the involved portion of colon⁵⁹ after localizing the site of hemorrhage endoscopically with a tagged red blood cell scan or with angiography, because these patients are likely to bleed again. If the site of bleeding cannot be determined definitively as left or right sided, a subtotal colectomy is the procedure of choice.⁶⁰

Diverticulitis

7 The treatment of diverticulitis typically parallels the Hinchey classification ([Algorithm 69-1](#))⁴⁴:

- Stage I, confined pericolic abscess: antibiotics and bowel rest
- Stage II, pelvic or retroperitoneal abscess: percutaneous abscess drainage
- Stage III, purulent peritonitis: resuscitation and urgent operation
- Stage IV, feculent peritonitis: resuscitation and urgent operation

Stage I diverticulitis is mild when patients can tolerate a diet, have no systemic symptoms (no fever, tachycardia, hypotension), and have no substantial peritoneal signs. The CT scan shows either minor pericolic fat stranding or wall thickening in the presence of diverticulosis. Outpatient management is usually appropriate for these patients. Broad-spectrum oral antibiotics are prescribed for 7 to 10 days, and patients start a clear liquid diet, advancing to a solid diet as symptoms resolve. If this is a first episode of presumed diverticulitis, an elective confirmatory study with either barium enema or colonoscopy is planned after inflammation has subsided. Progression of symptoms on this regimen warrants hospital admission and repeat CT scan may be necessary. The vast majority (70% to 100%) of patients with uncomplicated diverticulitis will recover without operative intervention. Although nearly a third will relapse, long-term fiber supplementation appears to reduce this risk.⁶¹

Severe stage I inflammation is indicated by intolerance of diet, possible nausea and vomiting, fever, chills, and peritoneal signs on examination, which are often focal. The CT scan may show a phlegmon or contained pericolic abscess. These patients are admitted to the hospital for parenteral broad-spectrum antibiotics. They are placed on bowel rest, intravenous fluids are administered, and if nausea and vomiting are major symptoms, a nasogastric tube may be placed. Analgesia is provided but limited to enable evaluation of symptom progression. In addition, since narcotics are known to cause strong, nonpropulsive sigmoid colon contractions, their use in patients with diverticulitis should be minimized. Small (<2 cm) pericolic abscesses may resolve with intravenous antibiotics; larger contained abscesses will likely require percutaneous drainage with CT (or possibly ultrasound) guidance.^{61,62} If a smaller abscess is treated initially with antibiotics only but symptoms fail to improve, percutaneous drainage should be considered. Progression of symptoms despite percutaneous drainage of an abscess usually indicates the need for surgery. Historically, 10% to 25% of patients requiring hospitalization for treatment of diverticulitis will not improve or will worsen with medical management alone; overall, 30% of hospitalized patients will require an operation. Those patients who recover from an initial episode of complicated diverticulitis (contained perforation or abscess) should be considered for single-stage, elective segmental colectomy after the resolution of acute inflammation.⁶³ As will be discussed further, minimally invasive surgical techniques are increasingly being used with good outcomes in these patients.

Patients who fail nonoperative management of diverticulitis or who present with purulent or feculent peritonitis require operative treatment. The goal of surgery in these patients – especially if they are toxic, developing multisystem organ failure, or hemodynamically unstable – is to resect the perforation and make a stoma. This defines a Hartmann procedure, in which the offending segment of colon is resected, a proximal stoma is constructed, and the distal colon and/or rectum are closed and left in the pelvis. The distal remaining segment of colon and rectum is referred to as a Hartmann pouch. This

approach was favored for many years because it is quick and simple and there is no chance of anastomotic leak. However, 30% to 50% of patients treated in this way never undergo reversal of the stoma, and when they do, the complication rate is high (major complications in 5% to 25%, anastomotic leak in 2% to 30%).^{64,65}

Algorithm 69-1. Diverticulitis Treatment based on Modified Hinchey Score (0–IV).

Despite these problems, this is still the procedure of choice in unstable patients. However, in the more stable patient who requires an urgent operation because of generalized diverticular peritonitis on presentation or failure of nonoperative management, the goal should be resection with primary anastomosis and creation of a diverting stoma, usually a loop ileostomy. The anastomotic leak rate in patients with free diverticular perforation who undergo a single-stage operation acutely is 13%.⁶⁶ While diverting ileostomy or colostomy upstream from a primary anastomosis does not prevent an anastomotic leak, it lessens the consequences of a leak by diverting the fecal stream from the area, preventing potentially devastating gross fecal soilage through the defect.

Obstruction

Complete obstruction from DD is unusual. Partial obstruction resulting from edema, spasm, and inflammation is more common. The differential diagnosis includes cancer and inflammatory bowel disease. Medical treatment and elective resection are usually successful. Rarely is the placement of a colonic stent necessary, but it may be used to allow for bowel preparation before a single-stage resection with primary anastomosis. A diverting stoma may be necessary to relieve obstruction and enable completion of the workup and treatment before definitive resection. If perforation has resulted from obstruction, even when the distinction between obstructive cancer and diverticular obstruction cannot be made, the perforated segment should be resected and diverting end-colostomy performed. If

this is a right-sided process in a relatively stable patient, primary anastomosis and diverting loop ileostomy can be considered.

Fistula

The presence of a fistula usually obviates the need for an emergency operation because the abscess has in effect spontaneously drained internally. A single-stage operation should be planned. The bladder side of a colovesical fistula is usually disrupted bluntly at the time of colon resection. No repair of the bladder is needed unless there is a visibly patent opening at the transected fistula tract site. A urinary drainage catheter is left in place for 7 to 10 days after surgery.⁴⁶ A cystogram can be done to verify closure of the tract opening and can facilitate discharge without an indwelling catheter following laparoscopic resection, which is often earlier than after open procedures. It is not necessary to leave a pelvic drain at the time of resection. Likewise, fistula tract openings to the vaginal cuff do not require closure. At most, omentum can be draped into the pelvis to separate the fresh colorectal anastomosis from the opening on the vagina.

Giant Colonic Diverticulum

Treatment is surgical resection of the involved segment of colon. Planned electively, a single-stage operation is indicated. Once perforated, the decision process parallels common diverticulitis, preference being given to resection with primary anastomosis and diverting loop stoma in the stable patient.

MANAGEMENT

Operative Strategies

8 The most important advance in the surgical management of DD besides trying to convert staged, emergency operations into elective, single-stage operations is the introduction of minimally invasive surgical techniques. No matter what the approach, certain challenges face the surgeon operating for DD. Inflammation distorts the anatomic planes. Dense fibrosis and adhesions impede sharp dissection and make it difficult to get good traction and countertraction that enable dissection. Inflammatory adhesions interfere with visualization and sometimes even palpation of anatomic structures.

Key concepts apply to both laparoscopic and open procedures. The goal is not to remove every diverticulum but rather to resect the area of inflammation or complication. The proximal resection line should be at soft, pliable bowel. The distal resection line must be at the top of the rectum demarcated by splaying of the bunched longitudinal muscle fibers (taenia coli) into the continuous longitudinal, outer layer of the rectal muscularis propria. The point of transection is almost never below the anterior pelvic peritoneal reflection. The splenic flexure should almost always be mobilized to facilitate creation of a tension-free colorectal anastomosis. The anastomotic site itself must be free from diverticula, which can be difficult in the patient with dense, pandiverticulosis. Manual, pinch dissection (or “finger fracture”) techniques are used to separate structures and divide areas of fibrosis and thick adhesions. Dissection commences away from the focus of inflammation, usually proximal to it. The left ureter should be identified as early as possible and before transecting major vessels or the colon. In the setting of severe inflammation in the left lower quadrant or pelvis, it can be very helpful to mobilize and divide the proximal bowel as an initial operative maneuver. Likewise, when dense inflammation makes the standard, lateral-to-medial mobilization of the sigmoid difficult, a medial-to-lateral approach can sometimes provide access to less inflamed tissues. While typically not needed, when a preoperative CT scan shows dense inflammation in proximity to the left ureter, placement of ureteral stents can help with ureteral identification and protection during dissection. Whether using open or laparoscopic techniques, an elective operation should be deferred for 4 to 6 weeks after the last episode of inflammation so that acute inflammatory changes do not interfere with either the dissection or the construction of a safe colorectal anastomosis.⁶⁷

There is growing experience with laparoscopic resection of even complicated DD. A meta-analysis comparing laparoscopic to open diverticulitis resections concluded that the laparoscopic patients had lower infection rates (overall and wound); decreased pulmonary, gastrointestinal, and cardiovascular complications; and a shorter time to recovery of bowel function and hospital discharge. Although studies in the meta-analysis included acute and chronic indications for surgery and complicated as well as uncomplicated diverticulitis in both groups, the authors cautioned that the retrospective nature of the

reviewed studies introduced selection bias.⁶⁸ When laparoscopic resections for DD are performed early (2 to 16 days after hospital admission), the conversion rates are higher than when surgery is delayed (more than 6 weeks).⁶⁹ Hand-assisted minimally invasive operations may offer significant benefit compared to pure laparoscopic surgery for DD, showing lower conversion rates, shorter operative times, and no compromise of the speedy recovery associated with fully laparoscopic operations.⁷⁰

Elective Surgery

Several observations form the basis of recommendations for elective resection following episodes of diverticulitis. Forty percent of diverticulitis patients admitted to the hospital will develop a complication, 23% following a single episode and 58% following two episodes. Thirty to 45% of patients hospitalized for diverticulitis will have another flare, usually within 5 years (90%). Among patients hospitalized a second time, only 10% remain symptom-free.^{71–73} Mortality doubles with a second flare. The classic indications for elective resection include two or more episodes of documented diverticulitis, a single episode of complicated diverticulitis (modified Hinchey stage Ib or II), one documented episode in an immunocompromised patient, one documented episode in a young patient (40 to 50 years old), and an inability to exclude cancer as the cause of the signs and symptoms.

9 Practice parameters outlined by the American Society of Colon and Rectal Surgeons note that most patients who present with complicated diverticulitis do so at their first episode, so operating on patients with uncomplicated episodes of diverticulitis may not reduce the risk of emergency surgery and mortality. “The age and medical condition of the patient, the frequency and severity of the attack(s), and whether there are persistent symptoms after the acute episode” may be better determinants of recommendation for elective resection.⁶¹ Complications develop often enough after successful medical management of complicated diverticulitis to warrant recommending elective resection.⁵⁶ Kaiser et al.⁴⁵ reported that 41% of patients treated with percutaneous drainage of a diverticular abscess will later develop severe sepsis.

It has been noted that the incidence of DD has steadily increased among young people, from 12% in 1969⁷⁴ to 20% in 1998⁷⁵ to 54% in a study of young and obese American patients in 2006.⁷⁶ Traditionally, elective colon resection was recommended for young people (age younger than 50 years) after one documented episode of uncomplicated diverticulitis. This recommendation was based on the belief that DD is more virulent in young patients. However, data are conflicting in this regard. There have been reports of young patients increased risk of complicated disease at presentation, increased frequency of recurrences (in the same time period as older patients, not as a function of longevity), and higher risk of needing emergency surgery and colostomy. Recommendation for elective resection following a single episode of uncomplicated diverticulitis in patients younger than 50 years of age was motivated by an interest in avoiding a colostomy and avoiding major morbidity and mortality. In view of conflicting data and adoption of technical strategies for avoiding end-colostomies in all patients, Nelson et al. have suggested following the same guidelines that are used for older patients.^{63,77–83}

10 Immunocompromised patients are more likely to fail medical management and must be watched closely since the manifestations of failure may be more subtle than in immunocompetent patients. Transplant patients, those on steroids or chemotherapy, diabetics, and dialysis patients are at risk. Elective resection in anticipation of transplant is also considered in some patients with DD. Interestingly, human immunodeficiency virus (HIV)-positive patients with normal CD4 counts appear to behave as if they were immunologically normal with respect to the incidence of diverticulitis and its clinical course. Since HIV infection has principally been an illness of younger people, most studies of diverticulitis have not included a large number of HIV-positive patients.⁸⁴ That may change as longevity improves with current antiretroviral regimens.

SUMMARY

DD is common and includes a spectrum of presentations and anatomic locations, favoring the left colon in Western societies. The etiology is likely multifactorial, with a low-residue diet being a common factor. The CT scan has dramatically improved diagnostic accuracy and helped with treatment planning. Treatment often parallels the Hinchey stage, particularly the modified Hinchey classification. Surgical treatment has evolved to favor medical management and image-guided percutaneous drainage of abscesses when feasible to convert surgical emergency-staged procedures into either single-stage procedures or procedures with primary anastomosis and diverting loop stoma. The distinction of

complicated DD and colon cancer can be difficult, but early contrast enema studies or colonoscopy can be safely performed and are the most helpful diagnostic procedures in this setting. The indications for elective resection following successful medical management of DD are being reconsidered, and it is becoming clear that elective sigmoid resection for DD should be offered to avoid recurrent symptoms, not primarily to avoid free perforation and the need for an emergent colostomy. Minimally invasive surgery is state of the art, and the hand-assisted techniques are particularly useful for elective DD resections.

Chapter 70

Anorectal Disorders

David J. Maron and Steven D. Wexner

Key Points

- 1 The most common manifestation of internal hemorrhoids is painless, bright red rectal bleeding associated with bowel movements. A high-fiber diet supplemented with bulk-forming agents may reduce symptoms of hemorrhoids and is ideal for first- and second-degree hemorrhoids.
 - 2 Rubber band ligation is suitable for symptomatic first- and second- and some third-degree internal hemorrhoids that do not respond to bulk-forming agents.
 - 3 Hemorrhoidectomy is required in only a few patients with symptomatic hemorrhoids. It should be considered when conservative therapy has failed, or when hemorrhoids are complicated by associated pathology such as ulceration, fissures, fistulas, large hypertrophied anal papillae, or extensive skin tags.
 - 4 Anal fissure is an ischemic ulcer in the lower portion of the anal canal; its treatment, both medical and surgical, involves relaxing the internal anal sphincter.
 - 5 Anal fistula is a chronic form of perianal abscess, spontaneously or surgically drained, in which the tract persists, with an internal opening at the dentate line and an external opening on the perianal skin.
 - 6 Rectal prolapse results from intussusception that extends beyond the anal verge. Fit patients are best treated with transabdominal rectopexy. Patients with significant medical comorbidities are best treated using a perineal approach.
 - 7 Anal condylomata acuminata are caused by human papillomavirus, as are anal intraepithelial neoplasia and anal cancers.
 - 8 Palpable lesions of the anal canal are not hemorrhoids and may be cancers; examination under anesthesia and biopsy allow for correct diagnosis.
-

ANATOMY AND PHYSIOLOGY

A detailed understanding of the anatomy and physiology of the rectum and anus is critical to accurate diagnosis and management of anorectal disorders.

The Rectum

The rectum begins at the level of the sacral promontory and measures approximately 15 cm in length. It descends along the curvature of the sacrum and passes through the levator ani muscles, where it becomes the anal canal. Although the rectum develops from the hindgut in conjunction with the sigmoid and left colon, it differs from the colon in that the outer muscular layer is continuous, characterized by the merging of the three taenia bands. The rectum has three lateral curves whose infoldings form submucosal folds in the lumen, known as the valves of Houston. Because of these curves, the rectum may gain 5 cm in length when straightened during resection.

The posterior aspect of the rectum lacks peritoneum and is directly adherent to the mesorectum. Anteriorly, the upper two-thirds of the rectum are covered by peritoneum; the lower third has no peritoneal covering. The level of the anterior peritoneal reflection (also referred to as the pouch of Douglas) is variable, but is usually 7 to 9 cm from the anal verge in men and 5 to 7 cm in women. The mesorectum is covered with a thin layer of investing fascia (fascia propria), which is distinct from the fascia overlying the sacrum. It is in this plane between these two fascial layers that a “total mesorectal excision” for rectal cancer is performed. The endopelvic fascia that covers the sacrum posterior to the rectum is also referred to as Waldeyer fascia; anteriorly, Denonvilliers fascia lies between the rectum and the vagina in females and the seminal vesicles in males (Fig. 70-1).¹

The Anal Canal and Sphincters

The anal canal is the terminal portion of the intestinal tract, and extends from the rectum for approximately 4 cm through the pelvic floor musculature to the hair-bearing skin of the anal margin. The circular smooth muscle layer of the rectum continues distally and thickens to form the internal anal sphincter (IAS), which extends to approximately 1.5 cm below the dentate line. The internal sphincter is surrounded by a continuous sheet of striated muscle of the pelvic floor, which is comprised of three distinct muscles – the puborectalis muscle, the levator ani muscle, and the external anal sphincter (Fig. 70-2). These muscles are critical both in the maintenance of continence and in defecation. The levator ani muscle is a broad, thin, funnel-shaped muscle that forms the floor of the pelvic cavity (Figs. 70-3 and 70-4). The puborectalis muscle originates on the posterior aspect of the pubic bones and forms a u-shaped sling around the anal canal that helps to maintain an acute angle between the rectum and anus. The external sphincter is an elliptical-shaped muscle that extends from the coccyx (anococcygeal ligament) around the internal sphincter. The external sphincter extends slightly caudad to the IAS, thereby forming the intersphincteric groove at the anal verge. The superficial fibers of the external anal sphincter insert into the skin of the anal verge as the corrugator cutis ani. The perineal body lies at the central portion of the perineum where the external sphincter, bulbospongiosus, and transverse perineal muscles meet and separates the anus from the vagina.

The lining of the anal canal contains different types of epithelium at different levels. At the anal verge, the skin becomes anoderm, a squamous lining without hair. Approximately 2 cm from the anal verge, the dentate line appears as a comb-like line due to folds in the mucosa. These folds are named the columns of Morgagni, and typically contain a small pocket or crypt at the inferior end. The mucosa at this level is a mixture of squamous, transitional, and columnar epithelium; this is referred to as the anal transition zone. The mucosa of the upper anal canal is lined by columnar epithelium. The internal hemorrhoidal plexus lies deep to the mucosa within the anal canal.

Figure 70-1. Fascial attachments of the rectum.

Understanding the various types of epithelium within the anal canal is important for the diagnosis of both benign and malignant conditions of the anus. The histology of tumors of the anal canal is critical to understanding the typical behavior and management of the disease. Squamous cell lesions that arise at the anal margin are often treated as skin cancers (wide excision), whereas those arising within the anal canal are treated with chemoradiation. Adenocarcinomas of the anal canal typically arise from the upper anus and are treated similar to adenocarcinomas of the distal rectum. Fistulas of the anal canal typically originate from the crypts at the dentate line, however fistulas associated with Crohn's disease will often arise from the columnar epithelium of the upper anal canal, and those associated with hidradenitis will originate from the mucosa or skin below the dentate line.

Figure 70-2. Arrangement of the external sphincter muscles.

The rectum and anus receive abundant blood supply from the superior, middle, and inferior rectal arteries (Fig. 70-5). The superior rectal (hemorrhoidal) artery starts as the terminal branch of the inferior mesenteric artery, descending posterior to the rectum where it bifurcates to supply the rectum and upper anal canal. The middle rectal arteries arise from the internal pudendal or inferior gluteal arteries (branches of the internal iliac artery). The inferior rectal arteries also arise from the internal pudendal arteries (in Alcock canal) and traverse the ischioanal fossa to supply the anal sphincters and anal canal. There are multiple communications among these three vessels.

The venous drainage of the anus is via both the portal and system venous systems (Fig. 70-6). The superior rectal vein drains the rectum and upper anal canal into the portal venous system through the inferior mesenteric vein. The middle and inferior rectal veins drain into the systemic venous system via the internal iliac veins. Because of the rich communication between these veins, patients with portal hypertension may develop porto-systemic shunts resulting in bleeding rectal varices.

Figure 70-3. Anatomy of the anal canal.

Lymphatic drainage of the rectum and anus mirrors the arterial supply (Figs. 70-7 and 70-8). Drainage from the upper and middle rectum flows to the inferior mesenteric lymph nodes. The lower rectum and upper anal canal may drain to the inferior mesenteric nodes, or may drain laterally to the internal iliac nodes. Lymph from the anus below the level of the dentate line typically drains to the inguinal lymph

nodes, however drainage may also occur to the inferior mesenteric and internal iliac nodes. Clinically this drainage pattern is important in patients with squamous cell cancers of the anus, as palpation of enlarged inguinal lymph nodes may signify metastatic disease.

The rectum and urogenital organs are supplied by a vast network of both sympathetic and parasympathetic nerves (Fig. 70-9). The sympathetic nerves branch from the sympathetic trunk from the first three segments of the lumbar spinal cord and synapse at the preaortic plexus. Some postsynaptic nerves innervate the upper rectum, while others travel distally to form the hypogastric plexus, which extends laterally along the rectum to form the pelvic plexus. The parasympathetic nerves (nervi erigentes) originate from the second, third, and fourth sacral nerve roots. These nerves then join the sympathetic nerves in the pelvic plexus to supply both the lower rectum and urogenital organs. This plexus lies within the lateral attachments of the rectum and along Denonvilliers fascia.

Figure 70-4. Muscles of the pelvic floor.

Preservation of both the hypogastric and pelvic plexuses during proctectomy is essential in maintaining normal sexual function.² In men, parasympathetic innervation is responsible for erection, while a complex interaction between sympathetic, parasympathetic, and somatic pathways produces ejaculation. Injury to the nervi erigentes may result in impotence, while injury to the hypogastric sympathetic trunks may cause retrograde ejaculation. Injury to the pelvic nerves may also lead to bladder dysfunction. In women, dysfunction following nerve injury is less well understood, however some patients do report dyspareunia and decreased lubrication during intercourse following pelvic surgery.

The IAS receives both sympathetic and parasympathetic nerves, and maintains tonic contraction at rest. The external anal sphincter is innervated by the inferior rectal branch of the pudendal nerve and perineal branch of the fourth sacral nerve. The inferior rectal nerve also carries sensory information from the anal canal. The majority of sensory nerve endings within the anal canal are located distal to the dentate line, however patients may sense painful stimuli up to 1.5 cm proximal to this area. Clinically this anatomy is relevant, as external hemorrhoids (below the dentate line) are sensitive to touch, while internal hemorrhoids (above the dentate line) may often be manipulated (banding, etc.) without the need for anesthesia. In addition, sensory receptors within the anal canal allow the discrimination between solid or liquid stool and flatus.

Figure 70-6. Venous drainage of the rectum and anal canal.

Figure 70-7. Lymphatic drainage of the rectum.

Physiology

The principal function of the anus is the maintenance of continence and regulation of defecation. The physiology of the defecation and maintenance of continence are complex, and involve both voluntary and involuntary muscular activities. Continence is also affected by the compliance and tone of the rectum, the consistency and volume of the stool, the sensation of the anorectum, and the muscular activity of the pelvic floor muscles. The hemorrhoidal plexus may also contribute to continence by acting as a “cushion” to keep the anus closed. Alterations of any of these mechanisms of continence may result in impaired continence.

The primary function of the rectum is to act as a reservoir for stool until it is a socially acceptable time and place for evacuation. When stool enters the rectum from the colon and the rectum becomes distended, receptors within the puborectal muscle initiate the rectoanal inhibitory reflex. This distension leads to simultaneous relaxation of the IAS and contraction of the external anal sphincter, allowing the stool to descend toward the anal canal. This sphincter response allows for “sampling,” or determination by the sensory epithelium of the anal canal as to whether the distension is from gas or stool. If defecation is deferred, the musculature of the rectum relaxes, thereby decreasing the pressure within the rectum; this is referred to as accommodation.

Continence is maintained by the fact that the pressure within the anal canal is higher than the pressure within the rectum. This high-pressure zone (between 40 and 70 mm Hg) within the anal canal is primarily accounted for by the IAS, however the external sphincter and puborectal muscle contribute as well. Autonomic innervation keeps the internal sphincter under tonic contraction and cannot be altered by voluntary control. Contraction of the external anal sphincter will often more than double the intra-anal pressure, however this muscle can typically be contracted voluntarily for only 40- to 60-second periods. The angle between the anus and rectum also may aid in the maintenance of continence by creating a flap valve and preventing stool from entering the anus. This anteroposterior angle is maintained by the contraction of the sling-shaped puborectalis muscle.

Figure 70-8. Lymphatic drainage of the anal canal.

Defecation involves both voluntary and involuntary mechanisms. If the call to defecate is answered, either the sitting or squatting position is assumed, thereby helping to straighten the anorectal angle. Straining by increasing the intra-abdominal pressure leads to a reflex relaxation of the puborectal muscle which further opens the anorectal angle and shortens the anal canal. Both the internal and external anal sphincters relax, the pelvic floor descends, and a funneling occurs, allowing the rectal contents to be expelled. After completion of rectal evacuation, a “closing reflex” occurs, where transient contraction of the external anal sphincter and puborectalis help to restore tonic contracture of the IAS (Fig. 70-10).

Diagnostic Evaluation of the Anus

Accurate diagnosis of anorectal disorders requires a detailed history and physical examination, and may include both anatomical and functional testing. Underlying illness or medication use may present with symptoms in the anal area, and it is important to know about travel history and sexual activity. The most common presenting symptoms of anorectal disease are pain, bleeding, discharge, and change in bowel habits.

Figure 70-9. Sympathetic and parasympathetic nerve supply of the rectum.

Bleeding may be seen as the result of an anal condition, or may represent bleeding from a more proximal source in the gastrointestinal system. Obtaining a history of the type and frequency of bleeding may help in making the diagnosis. Bleeding that is bright red and is not mixed with the stool may indicate an anal source, while blood in the form of clots or melena is more indicative of a colonic source. Even in patients with rectal bleeding in whom an anal disorder is found, it is important to consider colonoscopic evaluation of the colon to exclude other sources, particularly in patients who are at increased risk for cancer.

Anal pain associated with swelling that may or may not be related to defecation may be indicative of a thrombosed external hemorrhoid or an abscess. Pain that occurs during or immediately after defecation is often secondary to an anal fissure. Episodic pain (unrelated to bowel movements) that lasts for a short duration may be due to a condition known as proctalgia fugax or levator ani syndrome.

Physical examination of the anus should include a visual inspection of the perianal area as well as a digital examination ([Table 70-1](#)). Patients can be examined in either the left lateral decubitus or prone jack-knife position. Simple explanation and reassurance about the planned examination helps to ensure cooperation of the patient and minimize discomfort. Inspection of the anus may demonstrate skin tags or external hemorrhoids, fissures, scars, or excoriation of the skin. Straining during inspection may help to demonstrate rectal prolapse or perineal descent. Digital examination with a well-lubricated gloved index finger will give information including the tone of the anal sphincters as well identification of any rectal masses.

More detailed evaluation of the anus includes anoscopy, rigid or flexible proctosigmoidoscopy, and ultrasonography, as well as physiologic tests such as anal manometry, electromyography, pudendal nerve assessment, and defecography. Use of these tests for specific conditions will be discussed later in the chapter.

BENIGN ANORECTAL DISEASE

Hemorrhoids

Hemorrhoids are cushions of vascular tissue found in the anal canal found from birth. Histologically,

this tissue contains vascular structures whose walls do not contain muscle, and are therefore considered sinusoids instead of veins. The number and location of hemorrhoids may vary, however most commonly there are three pillars located in the left lateral, right anterior, and right posterior quadrants.

The term “hemorrhoids” typically refers to clinical situations where these vascular cushions are abnormal and cause symptoms. External hemorrhoids are defined by their location distal to the dentate line and are covered with squamous epithelium. Although these may swell and make anal hygiene difficult, they may also cause pain secondary to formation of clot within the sinusoid (thrombosed external hemorrhoids). Internal hemorrhoids are located proximal to the dentate line and are covered by transitional epithelium. As there are no somatic nerve endings here, internal hemorrhoids do not cause pain, but may present with bleeding or downward displacement of the cushion during defecation (referred to as prolapse). Hemorrhoids are classified according to the degree of prolapse ([Table 70-2](#)).

Figure 70-10. Mechanics of defecation.

Clinical Manifestations

1 Although patients may present with complaints of “hemorrhoids,” many of the symptoms of pain, itching, burning, and swelling may not be related to hemorrhoidal disease, instead being due to anal fissure, prolapsed anal papilla, or pruritus ani. The most common symptoms of internal hemorrhoids are bleeding with bowel movements and prolapse of tissue with defecation. Patients will often describe blood dripping into the bowl and staining the toilet water bright red. After passing a firm stool or a forceful straining, bleeding may continue with bowel movements for several days and then resolve for a variable length of time. It is rare that hemorrhoidal bleeding is severe enough to result in anemia. Patients may also complain of a sensation of incomplete evacuation of the rectum, and in chronic cases of prolapse may complain of mucous drainage or incontinence.

Physical examination should include inspection both at rest and during straining, digital rectal examination, and anoscopy. Evaluation may be performed in either the left lateral or prone jack-knife position. Inspection will help to exclude other pathology, including anal fissure, external opening of an anal fistula, and perianal excoriation, as well as to evaluate for the presence of skin tags, external hemorrhoids, and prolapse. Internal hemorrhoids are soft and cannot be reliably diagnosed with the

examining finger, however digital rectal examination may help to rule out a low rectal or anal neoplasm. If prolapse is present, it is possible to reduce the hemorrhoidal tissue during the examination. Anoscopy provides definitive examination of the anal canal, however this should be avoided in patients with anal pain due to fissure or abscess. While anoscopy may provide the diagnosis of hemorrhoids or other intra-anal pathology, patients presenting with rectal bleeding should also undergo assessment of the large intestine. In young patients, a flexible sigmoidoscopy may be sufficient, however in patients over the age of 50, those with significant risk factors for polyps or malignancy, or patients with inflammatory bowel disease, a colonoscopy should be performed.

Table 70-1 The Complete Digital Rectal Examination

Preparation
Enema
Left lateral decubitus position
Lighting, gloves, lubrication, anoscope
Visualization
Retract the buttocks
Inspect for:
Soiling
Excoriation or abrasion
Scarring
Patulous anus, deformity or flattening of folds
Fissure
External fistula opening
Anal wink reflex
Prolapse through anus with strain
External hemorrhoids
Palpation
Slow insertion of gloved, lubricated finger
Pain with examination
Palpable sphincter defect
Perineal body scarring
Anal stenosis
Relaxed or increased tone
Prostate abnormalities (men) or anterior rectocele (women)
Gross blood present
Muscle function: squeeze
Adequate
Accessory muscle use
Strain
Adequate
Puborectalis relaxation
Prolapsing tissue
Other organ prolapse

CLASSIFICATION

Table 70-2 Hemorrhoids Classification

Degree	Description
First	Hemorrhoids bleed but do not prolapse
Second	Hemorrhoids prolapse on straining but reduce spontaneously
Third	Hemorrhoids prolapse and require manual reduction
Fourth	Prolapsed hemorrhoids cannot be manually reduced

Treatment

Depending on the severity of the symptoms and the grade of the hemorrhoids, patients may be treated through nonoperative measures, office-based procedures, or operative therapy.

Nonoperative Management

As constipation and excessive straining during defecation are often the underlying causes of hemorrhoids, symptoms can be reduced or eliminated in many patients by altering their dietary intake and lifestyle. This goal is often achieved in patients with grade 1 or 2 hemorrhoids by increasing fluid and fiber in the diet, increasing physical exercise, and adding supplemental fiber. Fiber helps to add moisture to the stool to decrease constipation, and the addition of fiber has been shown in a double-blind, placebo controlled trial to be effective in reducing hemorrhoidal bleeding.³ Warm sitz baths, suppositories, and topical creams or ointments may also help to alleviate symptoms, however they often do not provide a long-term solution.

2 In patients with first-, second-, or third-degree internal hemorrhoids with no symptomatic external disease who fail conservative therapy, office-based therapies such as rubber band ligation, sclerotherapy, or photocoagulation may be an option. Rubber band ligation can be performed through an anoscope in the office without the use of anesthesia. The band is placed around the hemorrhoid above the dentate line, causing localized ischemia of the intervening tissue (Fig. 70-11). More than one hemorrhoid may be banded at one time, however multiple synchronous bands may lead to increased pain. A portion of the hemorrhoid and the rubber band are passed during defecation 48 to 72 hours following application. Fibrosis that occurs at the site of the banding causes fixation of the remaining hemorrhoidal tissue, which helps to prevent further prolapse and bleeding. Relief of symptoms may be achieved in up to 80% of patients who undergo banding, however recurrence rates as high as 30% have been reported.⁴ Complications of hemorrhoidal banding include severe pain requiring removal of the band, increased bleeding, and thrombosis of the hemorrhoids. Severe perianal sepsis is a rare complication, and should be suspected in any patient who develops worsening pain, fever, or the inability to void.

Figure 70-11. Rubber band ligation of an internal hemorrhoid.

Sclerotherapy involves the injection of a sclerosing agent into the submucosa that leads to fibrosis of the surrounding tissue. Many different injection agents have been described, however phenol is most commonly used. Injection is performed through an anoscope, and may be an option for symptomatic hemorrhoids that are too small to band. It is important not to inject the sclerosant directly into the hemorrhoids or thrombosis may ensue. Infrared photocoagulation causes thrombosis and tissue destruction within the anal canal. The probe is applied just proximal to the internal hemorrhoids through an anoscope. Results with both sclerotherapy and photocoagulation are varied and tend to be temporary only.

Operative Treatment

3 Excisional hemorrhoidectomy should be considered in patients who fail conservative or office-based procedures, who have combined internal and external hemorrhoids, who have hemorrhoids that require manual reduction (grade 3), or who have associated pathology such as ulceration, fissures, or fistulas.

Hemorrhoidectomy is typically an outpatient procedure, and in most cases local or regional (spinal) anesthesia may be used, however general anesthesia may also be employed. The patient is placed in the prone jack-knife position with the buttocks taped apart. An elliptical incision is made, beginning on the anoderm to remove any external component of the hemorrhoid, and is continued to the base of the hemorrhoid above the dentate line (Fig. 70-12). It is critical to preserve the underlying IAS muscle, as damage to the IAS may lead to postoperative incontinence. One, two, or three hemorrhoidal bundles may be excised at once, however it is also critical to ensure that normal anoderm is left between the excision sites; failure to preserve this anoderm may lead to postoperative anal stenosis. The dissection may be undertaken with the use of a scalpel, scissors, electrocautery, or controlled electrical energy such as ultrasonic shears or a bipolar vessel sealing device. The wound may be left open or, more commonly, may be closed with absorbable suture.

Excisional hemorrhoidectomy is superior to office-based therapies in achieving complete remission of hemorrhoidal symptoms, however complications including stenosis and hemorrhage are more common.⁵ Patients who undergo hemorrhoidectomy are also less likely to require multiple treatments. Surgical treatment of hemorrhoids can unfortunately also result in significant postoperative pain, and patients often require narcotic pain medication and may require up to 2 to 4 weeks to recover.

Stapled hemorrhoidopexy, while initially described as a treatment of mucosal prolapse, is also an option for prolapsing and bleeding hemorrhoids. Also known as the Procedure for Prolapse and Hemorrhoids (or PPH), this technique involves the removal of a circumferential sleeve of mucosa and submucosa of the distal rectum and anus. A circular stapler creates an anastomosis which elevates the anal canal and fixes the anal cushions into their normal anatomic positions. Because the resection is performed above the level of the dentate line, this technique is advantageous as it may result in less postoperative pain. It has no effect on external hemorrhoids, and therefore its use is somewhat limited.

Stapled hemorrhoidopexy is begun by placing a purse string suture in the mucosa and submucosa approximately 4 cm above the dentate line, incorporating all the redundant tissue circumferentially (Fig. 70-13). Correct placement of this suture is critical to prevent placement of the stapler too close to the dentate line, which can result in chronic pain. The anvil of a specialized circular stapler is then passed above the purse string, and the suture is used to pull the mucosa and submucosa into the stapler head. The stapler is then fired, which excises the sleeve of tissue and creates the anastomosis.

Figure 70-12. Technique of internal closed hemorrhoidectomy. **A:** Exposure of hemorrhoid with elliptic excision starting at perianal skin and extending to anorectal ring. **B:** Submucosal hemorrhoidal plexus dissected from the internal sphincter, anoderm, and mucosa. **C:** Wound closed with a running suture.

A meta-analysis of prospective randomized studies demonstrated that when compared with excisional hemorrhoidectomy, stapled hemorrhoidopexy offers some short-term benefits including less postoperative pain and earlier return to normal activity.⁶ In long-term follow-up, however, stapled hemorrhoidopexy has been associated with a higher rate of recurrent symptoms. Although PPH has been associated with several unique complications (rectovaginal fistula, staple line bleeding, and chronic pain), the overall rates of postoperative complications did not differ between the procedures.

Doppler-guided transanal hemorrhoid devascularization involves suture ligation of each hemorrhoidal column with resection of the hemorrhoid. A specific anoscope that includes a Doppler probe is used to identify the signal of the vessel feeding each hemorrhoidal column, typically above or just at the top of the column. Once the vessel is identified, it is then ligated with a suture and the Doppler probe is again used to confirm the disappearance of the signal. Typically the hemorrhoidal column is then also oversewn with this suture. The purported benefit of this procedure is that because the ligation occurs above the dentate line, postoperative pain should be significantly lower than with an excisional hemorrhoidectomy. Long-term results with this procedure are limited, however some authors have reported effectiveness in 90%.⁷

Figure 70-13. Stapled circular hemorrhoidectomy or procedure for prolapsing hemorrhoids. **A:** A purse-string suture is placed in the rectal mucosa proximal to hemorrhoids. **B:** The stapler anvil is placed proximal to the purse string, and the purse string is tied down to draw hemorrhoidal tissue into the staple line. **C:** The stapler is fired and removed, excising a sleeve of distal rectal tissue and creating a stapled anastomosis.

Figure 70-14. **A, B:** Excision of the entire thrombosed hemorrhoid.

Special Hemorrhoid Situations

Thrombosed External Hemorrhoids. Thrombosed external hemorrhoids are a relatively common complication of hemorrhoidal disease. The exact etiology is unknown, however their presence is often associated with physical exertion or straining (heavy exercise, moving or lifting furniture) or a bout of

severe constipation. Patients typically present with a painful, tender mass in the perianal area. Frequently, the thrombosis will lead to necrosis of the overlying skin and patients will complain of bleeding that is independent of bowel movements.

The management of thrombosed external hemorrhoids depends on when in the course of the disease the patient presents. The pain associated with this condition typically peaks within 48 hours and normally begins to subside after 4 days. If left untreated, the clot in the thrombosed vessels will dissolve within several weeks. Following resolution, large thrombosed hemorrhoids may remain as skin tags.

Because this condition is self-limiting, management is typically conservative and includes pain control with a mild analgesic, warm sitz baths, and a bulk-producing agent (usually psyllium fiber). If the patient presents within the first 48 hours, the procedure of choice is excision of the entire thrombosed hemorrhoid (Fig. 70-14). This procedure may be performed in the office or emergency room with the use of a local anesthetic. Using scissors, the thrombosed hemorrhoid is excised with the underlying vein; it is important to excise the entire thrombus in order to prevent recurrence. The skin edges are then reapproximated with the use of an absorbable suture or may be left open.

Incarcerated Hemorrhoids. Rarely, patients will present with prolapsed fourth-degree hemorrhoids which have become incarcerated. While internal hemorrhoids do not typically cause pain, patients with incarcerated hemorrhoids often have severe pain and may develop urinary retention. Edematous prolapsed hemorrhoids are seen, often in combination with large external components as well. Traditionally this condition has been treated with an urgent or emergent hemorrhoidectomy, however there is concern that leaving inadequate anoderm between the excision sites may lead to postoperative stenosis. Instead, patients may be treated with oral or intravenous pain medications and stool softeners, allowing the edema to resolve and the prolapse to reduce. These patients should then be offered an elective hemorrhoidectomy to prevent recurrence.

Anal Fissure

5 Anal fissure is an ulcer-like tear in the mucosal lining of the anal canal distal to the dentate line. Although more commonly found in younger patients, fissures can occur at any age and equally afflict male and females. Fissures can be classified as acute or chronic, and as primary or secondary. Primary anal fissures are almost always located in the posterior or anterior midline, and are not associated with any underlying disease. Secondary fissures may occur in a lateral position, and should alert the clinician to the possibility of Crohn's disease, HIV infection, tuberculosis, syphilis, or a hematologic malignancy. Anal fissures that have been present for longer than 6 weeks duration are arbitrarily classified as chronic.

The exact etiology is not known, however several mechanisms are thought to lead to the development of anal fissure. Trauma to the anal canal appears to be the initiating factor, most commonly as the result of passage of hard stool, as a low fiber diet seems to be associated with the development of anal fissure.⁸ Fissure may also occur following prolonged bouts of diarrhea, or following childbirth, most likely the result of forces from the fetus on the anal canal.

Hypertonicity of the IAS with resultant ischemia has also been implicated in development of chronic anal fissure. Ninety percent of fissures are found in the posterior midline of the anal canal, where Doppler flow studies and cadaver vascular injections have demonstrated relatively low perfusion. Studies have shown that when compared with normal subjects, patients with chronic anal fissure have higher resting pressure of the IAS. If the pressure within the anal sphincter approaches or exceeds the intra-arterial pressure of the inferior rectal artery, this may lead to relative ischemia and the development of an ischemic ulcer. This theory is strengthened by the fact that reduction of anal pressure following sphincterotomy improves blood flow to the anal canal, thereby promoting healing of the fissure.⁹

Clinical Manifestations

Anal fissure typically presents with pain during defecation and rectal bleeding. Patients often describe the pain as knifelike or as a tearing sensation, which may persist for several hours or longer after bowel movements. Rectal bleeding is typically bright red, and is separate from the stool and often seen only after wiping. Constipation is a common complaint of patients with anal fissure, and is frequently both a precipitating event and a result of patients' fear of a painful bowel movement.

The diagnosis of anal fissure can be made on physical examination by gently spreading the buttocks

apart to visualize the anal verge. Fissures will appear as a longitudinal or oval-shaped tear and may be associated with a sentinel pile, a protruding skin tag at the distal end of the fissure. Fibers of the IAS may be visible in chronic anal fissures. Once a diagnosis of fissure has been made, digital examination or anoscopy adds little other than increased pain for the patient, and should therefore be avoided.

Management

Medical Management. Symptomatic relief of anal pain from fissures may be obtained by warm sitz baths two to three times per day. Topical anesthetics or anti-inflammatory ointments may also be of benefit. The majority of patients with acute anal fissure will respond to conservative measures including sitz baths and the addition of a bulking agent such as psyllium fiber. Acute anal fissures often heal within 6 weeks, although the recurrence rate approaches 20%.¹⁰

As anal fissure is associated with hypertonicity of the anal sphincter, medical therapy is directed at decreasing resting anal pressures. Nitric oxide is a potent neurotransmitter that induces relaxation of the IAS. Application of 0.2% nitroglycerin ointment twice daily has been shown to induce healing in as many as 85% of patients,¹¹ however, patient compliance is often low due to nitrate-induced headache. Calcium-channel blockers have also been shown to reduce anal pressures. Topical diltiazem or nifedipine has been shown to have healing rates equivalent or superior to nitroglycerin¹² without the associated side effects. Unfortunately, recurrence rates with all of these therapies approach 50% in many series.

Botulinum toxin is an endopeptidase that blocks acetylcholine release at the neuromuscular junction, resulting in temporary paralysis of skeletal muscle. Although its exact mechanism of action in smooth muscle is not understood, injection of the toxin also results in relaxation of the IAS. The technique, dose, and success rates have widely varied in the literature, however some authors have reported success in 60% to 80% of patients. The most common side effect is temporary anal incontinence, typically only to flatus. The use of botulinum toxin may be an option in patients who have failed topical treatment, but who may be at a high risk of complications from surgery.

Figure 70-15. Lateral internal sphincterotomy (open method). **A:** The fissure in the midline is left alone. **B:** With a speculum used to expose the left lateral quadrant, an incision is made through the subcutaneous tissue to expose both the subcutaneous external sphincter and the internal sphincter. **C:** The internal sphincter is incised to its full thickness; care is taken not to cut the external sphincter. **D:** The wound is closed.

Surgical Management. In patients with chronic or recurrent fissures that fail to heal with medical management, surgical intervention is warranted. The most commonly performed procedure is the lateral internal sphincterotomy, which is an outpatient procedure that may be performed under local, spinal, or general anesthesia. When performed in an open fashion, an incision is made overlying the anal sphincter complex in the lateral position away from the fissure (Fig. 70-15). The internal sphincter is identified, and a portion of the muscle is cut typically extending cephalad to the level of the apex of the fissure. The wound is then closed with an absorbable suture. The procedure can also be performed in a closed fashion, where the scalpel is inserted into the intersphincteric groove, turned horizontally, and used to cut the internal sphincter as the anal canal is stretched open with a speculum. Healing rates following sphincterotomy range from 90% to 100%, however, impairment of continence following the procedure

has been reported to be as high as 47%.¹³

In patients who are at high risk of experiencing postoperative incontinence, an alternative approach may be the use of an advancement flap. This procedure involves excision of the fissure, surrounding scar tissue, and any skin tags. A variety of flap configurations including V-Y, Y-V, house, and others have been employed to help close the defect. Healing rates following fissurectomy and advancement flap are comparable to those following sphincterotomy.

Anorectal Abscess

The vast majority of anorectal abscesses result from infection of the glands that empty into the anal crypts within the anal canal at the level of the dentate line. Other causes of anorectal abscess include inflammatory bowel disease, trauma including iatrogenic (usually gynecologic or surgical) trauma, infections such as tuberculosis and actinomycosis, and malignancy. Since these glands lie within the intersphincteric space, blockage of a duct results first in an intersphincteric abscess which can then spread to the surrounding spaces (Fig. 70-16). The most commonly encountered anorectal abscess occurs in the perianal area, followed in frequency by ischioanal, intersphincteric, and supralelevator (Fig. 70-17).

Figure 70-16. Pathways of infection start in the intersphincteric space (A) and then spread to perianal spaces, forming perianal abscesses (B).

Figure 70-17. Classification of anorectal abscess.

Clinical Manifestations

Most patients with anal abscess present with pain. In patients with perianal or ischioanal abscesses, pain may be accompanied by swelling and erythema. Conversely, patients with supralelevator abscess are less likely to present with swelling and may have accompanying fever. Patients with severe rectal pain may also develop urinary retention.

Management

Treatment of anorectal abscesses requires incision and drainage; antibiotics alone are ineffective and may allow the suppurative process to progress to a more complicated abscess. The use of antibiotics in conjunction with drainage may be considered in the patient with concomitant cellulitis or in immunocompromised patients.

Most patients with perianal abscesses can be treated in an outpatient setting under local anesthesia. An elliptical or cruciate incision is made over the most tender area or area of fluctuance, and the skin edges are trimmed to prevent early closure of the wound, and all loculations are drained. Routine culture of the drainage is not recommended. Packing is also not necessary; rather, patients are instructed to soak the area in warm water and simply keep the wound covered with gauze.

Patients with superficial ischioanal abscesses may be treated in a similar fashion, however patients

with deeper or more complex abscesses typically require an examination under anesthesia with drainage in the operating room. Less commonly, patients may present with bilateral ischioanal abscess, a condition referred to as a horseshoe abscess. These infections typically begin in the deep postanal space, which spread to both ischioanal areas. Treatment requires that the deep postanal space be drained, which is accomplished by making a longitudinal incision in the skin between the tip of the coccyx and the anus and exposing the anococcygeal ligament. The ligament is then divided and the deep postanal space drained; counter incisions are then made overlying the ischioanal areas as well.

Patients with intersphincteric abscess often present with severe anorectal pain, however no indurated or fluctuant area is evident. These patients also typically require an examination under anesthesia. In the operating room, an intersphincteric abscess can be diagnosed by palpation of a protrusion into the anal canal or aspiration of purulent fluid from the intersphincteric space. Drainage is performed by dividing a portion of the internal sphincter muscle along the length of the abscess cavity.

Suprlevator abscesses are less common and can often be difficult to diagnose. Because the location of the abscess is adjacent to the abdominal cavity, patients may present with abdominal or pelvic pain. Digital examination may demonstrate induration or a tender mass located in the distal rectum above the level of the anorectal ring. The etiology of a suprlevator abscess dictates its management. These abscesses may result as an extension of an intersphincteric abscess, extension of an ischioanal abscess, or may result from an intra-abdominal abscess from perforated diverticulitis, appendicitis, or Crohn's disease. Suprlevator abscess secondary to extension from an ischioanal abscess should be drained through the ischioanal area. Suprlevator abscess secondary to extension from an intersphincteric abscess should be drained into the rectum, as drainage through the ischioanal area may result in a complex suprasphincteric fistula. Percutaneous drainage may be an option in patients with suprlevator abscess secondary to an intra-abdominal source.

Rarely, anorectal abscess can result in necrotizing infection and death, a condition referred to as Fournier gangrene. This situation may result from a delay in diagnosis and management of an anorectal abscess, infection with a highly virulent organism, or may be due to patient factors such as diabetes or compromised immune function. The infection superficially spreads around the perineum, causing necrosis of the skin and underlying muscle and fascia. Treatment includes empiric broad-spectrum intravenous antibiotics and prompt surgical debridement of the necrotic tissue until healthy tissue is encountered.

Anal Fistula

6 A fistula is generally defined as an abnormal communication between two epithelialized surfaces. Anal fistula (or fistula-in-ano) represents a communication between the anorectal canal and the perianal skin as the result from spontaneous or surgical drainage of an anorectal abscess. The incidence of fistulas following abscess drainage ranges from 5% to 83% in the medical literature, but is generally thought to occur in one-quarter to one-third of patients.¹⁴ Anal fistulas may also occur in up to 30% of patients with Crohn's disease.

Classification

Treatment of anal fistulas is in part dictated by the type of fistula. Fistulas are classified by their relation to the anal sphincter complex (Fig. 70-18).¹⁵ The most common type is the intersphincteric fistula, followed by transsphincteric, suprasphincteric, and extrasphincteric (Box 70-1).

Clinical Manifestations

The majority of patients with anal fistula have a history of previous anorectal abscess which either spontaneously drained or were surgically incised. Recurrence of anorectal abscess in the same location often indicates the presence of an underlying fistula. Patients complain of drainage, intermittent swelling, pain with defecation, and occasional bleeding. Physical examination often demonstrates an external opening on the perianal skin with granulation tissue. Drainage of fecal, purulent, or serosanguinous drainage may be evident or can be elicited with digital rectal examination or compression of the fistula tract.

Figure 70-18. The four main anatomic types of fistula.

Box 70-1 Classification of Anal Fistulas

Intersphincteric Fistula. The tract of the fistula lies within the intersphincteric space and the external opening lies close to the anal verge. These fistulas are the most common, and typically result following a perianal abscess.

Transsphincteric Fistula. The fistula tract begins in the intersphincteric space and then traverses through a portion of the external sphincter muscle. The external opening typically lies over the ischioanal fossa.

Suprasphincteric Fistula. The fistula tract begins in the intersphincteric space and then passes upward above the external sphincter and then perforates the levator ani muscles to drain through the ischioanal fossa.

Extrasphincteric Fistula. The fistula tract begins in the distal rectum rather than the anal canal and perforates the levator ani muscles to drain through the ischioanal fossa. These fistulas are rare and develop typically from Crohn's disease or rectal trauma.

Hidradenitis suppurativa may present in a similar fashion to anal fistula, with multiple openings on the perianal skin with surrounding induration. Unlike anal fistulas, however, any tracks associated with hidradenitis are superficial and do not communicate with the anal canal. A pilonidal sinus with perianal extension may also mimic an anal fistula, but in this situation the tract moves superiorly, away from the anal canal. Much less commonly actinomycosis can mimic a complex fistula.

Examination under anesthesia is recommended in order to treat any undrained abscess and to identify the internal opening. Flexible sigmoidoscopy may also be performed to evaluate for concomitant inflammatory bowel disease or malignancy. Under anoscopic guidance, a fistula probe can be inserted into the external opening through the fistula tract to determine the location of the internal opening. Goodsall rule states that if an imaginary line is drawn transversely across the anus, an external fistula opening seen posterior to this line will originate from an internal opening in the posterior midline, whereas an opening anterior to this line will originate from the closest anal crypt ([Fig. 70-19](#)).

Locating the internal opening is not always possible with a fistula probe, and in this situation other diagnostic maneuvers may be necessary. Injection of the external opening with hydrogen peroxide either with or without the use of endoanal ultrasound may help identify smaller fistulas. For patients with multiple or complex fistulas, fistulography with a water soluble contrast and fluoroscopy has been described, although the use of magnetic resonance imaging has largely replaced this.

Figure 70-19. Goodsall's rule for anal fistula.

Management

Options in the surgical treatment of an anal fistula include fistulotomy, cutting seton, fibrin glue, collagen plug, ligation of the intersphincteric fistula tract (LIFT), and advancement flaps. Specific treatment is dictated by the path of the fistula and the amount of sphincter complex that is involved in the tract. Any division of the sphincter muscle during treatment of a fistula carries with it a risk of impaired continence. Patients at higher risk of incontinence include those with pre-existing impaired continence (elderly patients and women with a history of episiotomy) and patients with chronically loose stools (colitis and Crohn's disease). The location of the fistula is also important; the sphincter complex is shorter anteriorly in women, and division of muscle here is particularly risky.

Simple submucosal, intersphincteric, and low transsphincteric fistulas may be managed with fistulotomy with very low risk of postoperative incontinence. Under regional or general anesthesia, the patient is placed in the prone jack-knife position. A fistula probe is inserted from the external opening to identify the internal opening at the dentate line. If there is no significant muscle overlying the probe, the tissue is incised and any granulation tissue is curetted. The wound is left open to heal by secondary intention, or the wound may be marsupialized by suturing the wound edges to the tract.

Fistulas that involve a significant portion of the sphincter muscle (high transsphincteric and suprasphincteric fistulas) are better managed in a staged fashion with the use of a seton. A seton is a suture or vessel loop that is passed through the fistula tract and is tied to itself to form a ring between the internal and external openings. The purpose of this is to facilitate drainage of the fistula and promote wound contracture. Setons may be used as a bridge to a more definitive procedure, or may be used in a "cutting" fashion. A cutting seton is tightened at regular intervals, gradually cutting through the sphincter muscle. In theory, this leads to fibrosis of the sphincter muscle rather than a retracted defect. This may be continued until the fistula has completely resolved, or a staged fistulotomy may be performed to divide the remaining sphincter muscle.

In an effort to minimize postoperative incontinence, fibrin glue and collagen plugs have been used in the treatment of anal fistulas. The mere existence of this plethora of therapeutic alternatives attests to the lack of satisfactory efficacy with all of them. Fibrin glue is made of a combination of fibrinogen, thrombin, and calcium. Injection of this into the fistula tract is thought to induce clot formation and promote the growth of collagen to close the fistula. Short-term success rates have been reported as high as 70%, however late recurrences despite initial healing are common.¹⁶ Fistula plugs made of porcine submucosal collagen inserted into the fistula tract are intended to provide a scaffold for the growth of fibroblasts to heal the fistula. Long-term healing with fistula plugs has also been disappointing, with success rates of only 30%,¹⁷ however, success rates may be higher in long fistula tracts.

LIFT is a surgical technique that avoids division of the sphincter complex. With the patient in the prone jack-knife position, a probe is passed through the fistula tract. An incision is then made in the intersphincteric groove directly overlying the probe, and plane between the two muscles is dissected. The fistula tract is then divided and ligated between the internal and external sphincter muscles. Success with this procedure has been reported as high as 88%.¹⁸ If the LIFT procedure fails, the fistula often recurs in the intersphincteric plane, thereby allowing treatment with a fistulotomy.

The use of endorectal advancement flaps has been advocated for high transsphincteric and suprasphincteric fistulas, fistulas associated with inflammatory bowel disease, fistulas in patients who have failed other treatments, and anterior fistulas in female patients. In this procedure, the fistula tract is either cored out or curetted, and the internal opening is identified and excised. A full-thickness flap of rectal mucosa and submucosa is raised and advanced, typically 1 cm below the level of the internal

opening. It is important to maintain adequate blood supply by creating a flap, the base of which is twice the width of the apex. Successful healing following an endorectal advancement flap has been reported in as high as 90% of patients, although much lower in patients with Crohn's disease and/or receiving steroids.¹⁹

Anal Fistula Associated with Crohn's Disease

Treatment of anal fistulas in patients with Crohn's disease can be particularly challenging. Surgical treatment of these fistulas is associated with poor wound healing and the risk of sphincter injury. Medical treatment of the underlying Crohn's disease is therefore extremely important in improving the chance of fistula healing. Antibiotics such as ciprofloxacin and metronidazole have been shown useful; 8 weeks of oral metronidazole has reportedly eliminated drainage, erythema, and induration in up to 80% of patients.²⁰ Treatment with azathioprine and methotrexate have been shown to have little impact on fistula healing. Infliximab, a monoclonal antibody against tumor necrosis factor- α , has been shown to be effective in Crohn's anal fistulas. Treatment with infliximab alone has been shown to reduce the number of draining fistulas by half in 62% of Patients with Crohn's disease (compared with only 26% of patients treated with placebo).²¹ When combined with surgical intervention, fistulas in patients treated with infliximab may heal faster than those treated with surgery alone.²²

Surgical intervention in patients with Crohn's anal fistulas should be conservative and limited initially to adequate drainage with liberal use of draining setons. Although fistulotomy for subcutaneous fistulas may be considered, active Crohn's disease within the rectum is associated with poor outcomes. Due to the high likelihood of recurrence or the development of additional fistulas, any division of the sphincter muscle should be avoided. Once any infection has been drained and the underlying Crohn's disease has been optimally controlled with medication, repair with either an endorectal advancement flap or LIFT may be an option. In rare cases of Crohn's anal fistulas, fecal diversion with a stoma or proctectomy may be warranted.

Rectovaginal Fistula

A rectovaginal fistula is a communication between the anterior wall of the anal canal or rectum and the posterior wall of the vagina. Obstetrical injury is the most frequent cause of acquired rectovaginal fistulas, however trauma, infection, and radiation may also result in their development (Table 70-3). Rectovaginal fistulas can be classified according to their location (Fig. 70-20). In low fistulas, the rectal opening is at or below the dentate line; in high fistulas, the vaginal opening is at or near the cervix. A second classification system is based on the location, size, and cause of the fistula (Table 70-4).

Figure 70-20. Rectovaginal fistula classified by location. Fistulas are low when located at or just cephalad to the dentate line, high when near the cervix, and mid when located in between.

ETIOLOGY

Table 70-3 Causes of Rectovaginal Fistula

Congenital maldevelopment
Trauma
Obstetric
Operative
Blunt and penetrating injury
Foreign body
Infection of anal canal or vaginal septum
Pelvic irradiation
Neoplasm

Clinical Manifestations

The clinical presentation of a rectovaginal fistula depends on the size and location of the fistula. In patients with small or low fistulas, the most common symptom is the passage of flatus from the vagina. Patients with large fistulas may complain of vaginal discharge with fecal odor, passage of flatus or stool from the vagina, recurrent urinary tract infections, or painful vaginitis.

Diagnosis is typically made on physical examination. Digital rectal examination or bimanual examination of rectum and vaginal may demonstrate the defect. Anoscopy may be helpful in visualizing the opening in low fistulas, while proctoscopy or flexible sigmoidoscopy may be required in mid or high fistulas. If a rectovaginal fistula is suspected clinically but no defect can be visualized, a methylene blue rectal enema may be administered following vaginal tampon insertion. Staining on the tampon is suggestive of a fistula. A contrast rectal enema under fluoroscopy may be needed in more complex cases to identify the fistula.

CLASSIFICATION

Table 70-4 Classification System Based on the Location, Size, and Cause of Rectovaginal Fistula

Characteristic	Simple	Complex
Location	Low to midvaginal septum	High vaginal septum
Size	2.5 cm or less in diameter	2.5 cm or more in diameter
Cause	Traumatic or infectious cause	Inflammatory bowel disease irradiation, neoplastic cause

Management

Spontaneous healing of rectovaginal fistulas may occur in some small fistulas that are secondary to obstetrical trauma. In these patients, it is important to wait 3 to 6 months before considering surgical repair, as this will allow resolution of any inflammation. Nonoperative healing is much less likely to occur in patients with fistulas secondary to inflammatory bowel disease or radiation. In patients with small fistulas and minimal symptoms, medical treatment with bulk agents such as fiber may be sufficient in controlling symptoms.

Treatment of low rectovaginal or anovaginal fistulas may be accomplished by endorectal advancement flap, vaginal advancement flap, or perineal procedures. Advancement flap is typically the initial procedure in patients without symptoms of incontinence. Most colorectal surgeons prefer to perform an advancement flap transanally rather than vaginally as the repair is to the high-pressure side. After the fistula site in the rectum is excised and closed, a rectal flap consisting of mucosa, submucosa, and a portion of the internal sphincter muscle is advanced to cover the opening in the rectal wall (Fig. 70-21). The opening in the vagina may be left open to drain. Success rates of endorectal advancement flaps for simple low rectovaginal fistulas are as high as 83%.²³

If a low rectovaginal fistula is associated with incontinence secondary to a defect in the anal sphincter, repair with an overlapping sphincter repair has been shown to have good results. Using this technique, an incision is made over the perineal body, and the plane between the rectum and vagina is developed. The cut ends of the anal sphincter are identified and mobilized. The fistula tract is excised and closed, and the ends of the sphincter muscle are reapproximated in an overlapping fashion. Patients with no evidence of sphincter defect who have failed endorectal advancement flap may be candidates for closure with an interposition graft. This involves closure of the fistula and placement of well-vascularized tissue between the rectum and vagina. The bulbocavernosus muscle (Martius flap) and gracilis muscle are the most commonly used muscle flaps. These latter procedures are usually performed

after a stoma has been created. The stoma is closed after healing has been documented by both rectal and vaginal contrast studies and examination under anesthesia.

Rectovaginal fistulas located higher in rectum often require a transabdominal repair. Simple fistulas with healthy surrounding tissue may sometimes be repaired by mobilization of the rectovaginal septum, division of the fistula, and layered closure of the rectal defect. Most cases, particularly larger fistulas and/or fistulas associated with Crohn's disease or radiation, will require resection of the rectum to below the site of the fistula as a low anterior resection with coloanal anastomosis. It may be useful in these cases to also place healthy tissue such as omentum or muscle between the rectum and vagina to prevent recurrent fistula. While patients with simple rectovaginal fistulas do not typically require fecal diversion, those with complex fistulas will often require creation of a colostomy in conjunction with surgical repair. Elderly patients or patients with severe Crohn disease may be better served by a permanent colostomy.

Pilonidal Disease

Pilonidal disease refers to a subcutaneous infection occurring in the midline of the sacrococcygeal area, the gluteal cleft. Pilonidal disease typically presents in young patients, occurs more frequently in men than women, and is more prevalent in hirsute individuals. The exact etiology of pilonidal disease is unknown, however it is believed to be related to hair. Pilonidal abscess or sinuses develop either from an infection within hair follicles in the area, or from a foreign-body reaction to hairs that become embedded in the skin.

Diagnosis

The presenting symptoms in many patients with *pilonidal abscess* are pain, swelling, and erythema near the top of the gluteal cleft. A *pilonidal sinus* occurs following spontaneous or surgical drainage of a pilonidal abscess, and present as a nonhealing wound or chronic drainage from the area. Early in the development, patients may complain of pain while sitting, and may have only mild cellulitis. A painful fluctuant mass can often easily be seen in patients with acute abscess. Chronic pilonidal sinuses can be visualized in the intergluteal fold. The majority of these tracts run cephalad, however occasionally a tract may run toward the anus; in these patients, it is important to differentiate pilonidal disease from hidradenitis suppurativa and anal fistula. Careful examination can demonstrate an opening or openings in the midline referred to as "pits," and likely represent either ruptured hair follicles or the site at which a hair shaft penetrates the skin.

Treatment

Incision and drainage is the treatment of choice for an acute pilonidal abscess. This can typically be done in the office with the use of local anesthesia, although rarely may require drainage in the operating room. A longitudinal or elliptical incision is made over the abscess, and any hair within the cavity is removed. Patients are instructed to clean the wound regularly and to cover the wound. Packing is not necessary. Antibiotics are not indicated, unless there is significant associated cellulitis.

Chronic pilonidal sinuses have been treated in numerous ways, however no one specific treatment has proved completely satisfactory. Nonoperative treatments that have been suggested include shaving or laser hair removal of the area surrounding the sinus until healing has occurred, although the efficacy of this strategy is unknown. The most common surgical treatments include wide local excision, excision with flap closure, or specialized procedures such as the Bascom procedure.

Wide local excision incorporates removal of the pilonidal sinus, any associated pits, as well as some normal surrounding tissue. The wound may be left open to heal by secondary intention, or may be primarily closed. Patients whose wounds are left open often require intensive wound care with wet-to-dry dressings and gentle debridement of devitalized tissue and exudates, and complete healing may take several months. In an effort to reduce wound healing times, the edges of the wound may be "marsupialized" by suturing the wound edges to the base. As the pilonidal sinus may be chronically infected, postoperative infection is a concern in patients with primary closure. In a randomized trial, patients who underwent primary closure had significantly higher rates of postoperative infection and recurrence when compared with those patients whose wounds were left open.²⁴

Figure 70-21. Endorectal advancement of anorectal flap. **A:** Exposure is gained by an anal speculum, and the fistula is identified. Outline of endorectal flap, extending proximally to 7 cm from the anal verge. **B:** The full-thickness flap is created to include the internal sphincter muscle. **C:** Lateral mobilization is made on each side in the submucosal plane. **D:** Anorectal wall on each side is approximated. **E and F:** The endorectal flap is pulled down to cover the wound and sutured. The fistula is excised. The aperture in the vagina is not sutured but is left open for drainage.

As excision often leads to a large defect, numerous flap closures have been described for pilonidal disease. These include a rhomboid rotational flap, gluteus maximus rotational flap, z-plasty, and an advancement flap of skin and gluteal fat (Karydakakis flap).²⁵ Excellent results have been reported from specialty centers using these approaches.

The Bascom procedure is based on the premise of removing the pilonidal disease while avoiding excision of large areas of normal tissue. This involves making a vertical incision at least 1 cm off the midline overlying the chronic cavity, without excising the walls of the cavity. The sinus tracts leading to the midline pits are probed and curetted to remove any granulation tissue. The midline pits are then excised and closed, while the lateral incision is left to close by secondary intention. Excellent results have been reported with this procedure,²⁶ however, no trials comparing this to other techniques have been published.

Rectal Prolapse

4 Rectal prolapse (procidentia) is a relatively uncommon condition in which there is a full-thickness protrusion of the rectum through the anal canal. A related condition is rectal intussusception, which is where the rectum telescopes into itself but not through the anus. Rectal prolapse is significantly more common in females than in males, and many patients have a long standing history of straining and constipation. Association with other pelvic floor conditions such as urinary incontinence, voiding disorders, and cystoceles is common. Prolapse is also more commonly found in patients with dementia, mental retardation, and schizophrenia.

Pathophysiology

The exact cause of rectal prolapse is not known, however it likely represents chronic progression of intussusception. As the rectum or rectosigmoid infolds onto itself, it progressively pulls the rectal wall away from its attachments to the sacrum and pelvic sidewall. With persistent straining, the bowel continues to intussuscept, eventually leading the entire wall of the rectum to evert through the anal opening. Studies of anorectal function in patients with rectal prolapse demonstrate that these patients often have impaired resting and voluntary squeeze pressures in the anal sphincter, decreased rectal capacity, impaired continence, and inadequate puborectalis relaxation during defecation. Incontinence is likely secondary to chronic mechanical stretching of the sphincters from the prolapse, stretch injury to the pudendal nerves, and loss of normal sensation of the anal canal. Several anatomic abnormalities are typically seen in patients with chronic rectal prolapse (Table 70-5), however, it is unclear whether these are factors that lead to prolapse or whether they are caused by the condition.

ETIOLOGY

Table 70-5 Anatomic Abnormalities in Rectal Prolapse

- Abnormally deep rectovaginal or rectovesical pouch
- Lax and atonic musculature of the pelvic floor
- Lack of normal fixation of the rectum and an elongated mesorectum
- Unusually redundant sigmoid colon
- Lax and atonic anal sphincter

Solitary rectal ulcer syndrome (SRUS) is a rare condition that is also likely related to intussusception of the rectum. The straining from constipation can lead to an ulcer in the anterior rectal wall from repeated mucosal trauma. In severe cases, SRUS may lead to gastrointestinal hemorrhage and chronic pain. Biopsies of these ulcers often demonstrate mucosal glands displaced within the submucosa, which may lead to the misdiagnosis of carcinoma.

Evaluation

The diagnosis of rectal prolapse is clinically made on the basis of the history and physical examination. Patients typically present complaining of a mass with defecation that may or may not spontaneously reduce. Prolapse is often associated with fecal or mucous soilage and pelvic discomfort; pain is not typically present. Digital rectal examination often demonstrates a patulous anus with decreased sphincter tone. Full-thickness rectal prolapse will appear as concentric rectal rings protruding through the anus (Fig. 70-22). It is important to differentiate full-thickness prolapse from prolapsed hemorrhoids or mucosal prolapse, which will appear as radial folds. If the prolapse is not obvious, it is best demonstrated by asking the patient to strain while seated on a commode. Anoscopy or proctoscopy will often show mildly inflamed mucosa or ulceration. Patients should be evaluated with a colonoscopy to evaluate for bleeding and to rule out a mass, which can rarely serve as the lead point of intussusception. For those patients with chronic constipation, a colonic transit study may help to determine whether colonic resection may be necessary. Anal manometry is not typically useful other than to document baseline function. When intussusception is suspected but cannot be visualized, defecography may be helpful and may demonstrate other related conditions such as enterocele or puborectalis dyssynergy. Patients with other pelvic floor complaints require further evaluation by urogynecology.

Management

Surgical intervention is the gold standard for treating full-thickness rectal prolapse, however nonoperative management with treatment of the constipation and pelvic floor strengthening exercises has been described in patients who are poor surgical candidates. While the objective is to resolve the prolapse, repair may also help to improve or restore fecal continence and correct functional constipation. Several different operations have been described for rectal prolapse, either from an abdominal or perineal approach. The benefit of a perineal approach is that it can be performed under regional anesthesia and generally is less painful than an abdominal approach. The perineal procedures may be ideal for older patients or those individuals who may not tolerate general anesthesia or major abdominal surgery. The trade-off is that the recurrence rates of a perineal approach are generally higher (up to 38%) than an abdominal approach (less than 12%).²⁷ Perineal repair of rectal prolapse includes the Altemeier perineal rectosigmoidectomy and Delorme plication. Abdominal approaches include rectopexy, with or without concomitant sigmoid colon resection.

Figure 70-22. Full-thickness rectal prolapse will appear as concentric rectal rings protruding through the anus.

Perineal rectosigmoidectomy (Altemeier procedure) is a transanal surgery in which the prolapsed rectum and redundant sigmoid colon are excised through the rectum. The procedure is typically performed in the prone jack-knife position and can be performed under general or spinal anesthesia (Fig. 70-23). The rectum and sigmoid colon are resected and a low anastomosis is performed just proximal to the dentate line. Ideally a levator muscle imbrication and a colonic j-pouch are performed prior to a stapled or hand-sewn anastomosis. The former maneuver may help improve continence while the latter adjunct may help decrease bowel frequency. Without these steps, loss of the compliant rectum combined with low resting anal sphincter pressures often results in incontinence, soiling, and urgency. Major long-term complications include recurrence, fecal urgency, tenesmus, and anastomotic stricture. Overall results vary, but there is some data to suggest that among the perineal approaches, the Altemeier procedure has the lowest recurrence rates and best functional outcomes.²⁸

The Delorme procedure is also typically performed in the prone position, and is useful in patients whose rectum does not prolapse more than 5 cm. This procedure involves stripping the mucosa of the prolapsed rectum from the muscularis propria, followed by plication of the muscularis propria and reanastomosis of the mucosal ring (Fig. 70-24). This procedure may also be combined with levatoroplasty or sphincter repair in an effort to improve functional outcomes. This technique has a high recurrence rate but has very low associated morbidity, and may therefore be useful in frail, older patients.

Figure 70-23. Perineal rectosigmoidectomy. The patient is placed in the prone jack knife position with both legs in gynecologic stirrups. **A and B:** A circular incision is made on the prolapsed rectum 2 cm proximal to the dentate line. **C:** The peritoneal attachment is dissected from the anterior rectal wall, thus opening into the peritoneal cavity. **D:** The mesorectum or mesosigmoid is clamped and divided laterally and posteriorly. **E:** This is followed by approximation of the puborectalis. **F:** The anterior wall of the protruding rectum is cut 1 cm distal to the anal verge. **G:** Stay sutures of 2-0 synthetic absorbable material are placed in four quadrants. **H:** Anastomosis with interrupted stitches; **I:** Colonic J pouch.

Transabdominal rectopexy involves a thorough mobilization of the rectum to the level of the pelvic floor musculature, followed by fixation of the mesorectum to the presacral fascia below the sacral promontory (Fig. 70-25). Fixation may be performed through a laparotomy or Pfannenstiel incision, or with a minimally invasive approach (laparoscopic or robotic assisted). Fixation of the rectum can be accomplished with suture, tacks, or the placement of a mesh (posterior to the rectum or as a supportive sling around the rectum). In patients with a history of chronic constipation and evidence of slow transit on colonic transit studies, rectopexy may be combined with resection of the sigmoid colon. In these cases, the anastomosis should be performed above the level of the rectopexy to reduce the risk of anastomotic complications. Recurrence rates following rectopexy are generally lower than 10%, and many patients will have improvement in fecal continence. While division of the “lateral stalks” during resection rectopexy seems to reduce recurrence rates, it may exacerbate constipation.

One multicenter cohort study of 643 patients who underwent an abdominal repair of rectal prolapse demonstrated pooled 5- and 10-year recurrence rates of 7% and 29%, respectively.²⁹ No difference was identified based on the degree of mobilization or resection. In addition, similar recurrence rates were seen in patients who underwent suture rectopexy and mesh rectopexy, and in patients who underwent open or laparoscopic repairs. Another abdominal approach, ventral rectopexy, has also been recently popularized for the treatment of rectal intussusception and prolapse. This procedure involves mobilization of the anterior rectum, with no or minimal posterior dissection, followed by anterior mesh placement and sacral fixation. This technique was devised in an effort to spare patients from the risk of autonomic complications associated with complete rectal mobilization. Published recurrence rates are similar to those for other abdominal approaches. The abdominal operations can be performed as open,

laparoscopic, or robotic procedures.

Fecal Incontinence

Fecal incontinence is an embarrassing and socially devastating condition that affects up to 18% of the population and up to 50% of nursing home residents.³⁰ Incontinence may be as severe as the involuntary passage of solid stool, but also includes patients who are unable to control the passage of flatus and those who suffer from chronic leakage that requires the use of pads. It is important to understand that fecal incontinence is not a diagnosis, but a symptom of which there are multiple potential causes.

Figure 70-24. Modified Delorme procedure. Patient is placed in the prone position. **A** and **B**: With a Pratt speculum used for exposure, a circumferential incision is made 1 cm proximal to the dentate line. The submucosa is dissected from the underlying internal sphincter. At the level of the anorectal ring, the Pratt speculum is replaced by Lonestar (r) retractors placed at a right angle to the dentate line. **C** and **D**: Proximal to the anorectal ring, the dissection continues in the mucosal plane until the mucosa resists being pulled down. The mucosal tube is then cut. **E** and **F**: With 2-0 synthetic absorbable sutures, the mucosa at the upper cut end is brought down to the mucosa at the lower cut end, taking along the denuded anorectal wall. Eight such sutures are placed all around. **G**: At completion of the anastomosis, the anorectum is plicated.

Anal continence requires a complex integration of function between the anal sphincters and pelvic floor (see Physiology), but is also dependent on the volume and consistency of the stool, the compliance of the rectum, and normal neurologic function. It is for this reason that a large volume of diarrheal stool entering the rectum may overcome anal continence, even in a healthy patient. Other disease states such as inflammatory bowel disease and radiation proctitis, as well as central nervous system pathologies such as spinal cord injury may also produce incontinence. Incontinence is far more common in female patients, although obstetrical tears of the anal sphincter may not present as incontinence for two or more decades following the injury. Injury to the pelvic floor muscles and pudendal nerves may also result following childbirth. Damage to the sphincter complex can result from surgical intervention (fistulotomy or internal sphincterotomy), trauma, or chronic stretching as seen in rectal prolapse.

Evaluation

A thorough history is important, as it will frequently lead the physician to the potential underlying causes of the incontinence. Obstetrical and surgical history should be noted, as well as any change in bowel consistency. It is helpful to quantify the frequency and degree of fecal incontinence with the use of a validated incontinence scoring system.³¹ Symptoms of other pelvic floor conditions including urinary incontinence, and rectal prolapse should also be elicited. Physical examination should include inspection of the perianal skin for scars from previous surgery or obstetrical injury, excoriation from chronic soiling, or large prolapsing hemorrhoids. Digital examination can provide a gross assessment of both resting tone and squeeze effort.

In addition to the history and physical examination, several tests of anorectal anatomy and physiology can be done to investigate the cause of incontinence. Endoanal ultrasonography can provide a circumferential anatomic image of the anal canal, including visualization of the internal and external sphincters and any defects in these. Anorectal manometry may help to establish a baseline of resting and squeeze pressures, and may help to identify decreased rectal compliance. Electromyography of the pelvic floor with evaluation of pudendal nerve terminal motor latency may help to identify a neurologic cause of incontinence. Defecography may aid in operative planning by identifying previously unrecognized disorders such as rectocele or intussusception. The evaluation of a patient with fecal incontinence must also include an assessment of the impact of the symptoms on the patient's quality of life. This is important because the need for intervention is often based on the patient's desires rather than a threat to his or her health.

Figure 70-25. Transabdominal rectopexy. After full mobilization of the rectum (A,B), the endorectal fascia and peritoneum on each side is sutured to presacral fascia, below the promontory of the sacrum (C).

Management

Patients with chronic diarrhea, neurologic conditions, or systemic illnesses are best treated medically. This treatment is generally directed at regulation of bowel habits, with the goal of decreasing the frequency of bowel movements. The addition of a fiber supplement adds bulk to the stool and absorbs fluid, creating a more solid stool that is easier to sense and to control. Constipating agents such as loperamide, diphenoxylate atropine, codeine, and bile acid binders may help to make stool harder and less frequent, thereby making it easier for the patient to control. In an effort to decrease leakage, some patients may benefit from the use of regular enemas to maintain an empty rectum.

Biofeedback is a pelvic floor retraining physical therapy program that can be very helpful in the treatment of patients with disorders of the pelvic floor. This “retraining” aims to provide increased strength to the sphincters, sensation of the anorectum, and coordination of the pelvic floor. Biofeedback typically employs the use of a pressure-sensitive probe placed into the anal canal to monitor the strength and coordination of the anal sphincter and pelvic floor musculature. The data from the probe are then transmitted to a monitor, where the patient is able to watch the manometric tracings. Through a series of coached exercises and visual feedback, improvements can be made in pelvic muscle control, threshold of sensation within the rectum, and overall control of defecation. Several studies have demonstrated the effectiveness of biofeedback in improving continence, with success rates ranging from 50% to 90%,³² however, results are often dependent on the quality of the therapist and the motivation of the patient.

Other options for patients with less severe fecal incontinence include radiofrequency treatment and the injection of biocompatible bulking agents into the anal canal. The Secca™ procedure involves the use of radiofrequency delivered to the anal sphincter, which results in tissue remodeling.^{33,34} Several case series have demonstrated the efficacy of this procedure, with more than half of patients treated reporting improvement in their symptoms.³⁵ Injection of a bulking agent (silicone or carbon-coated microbeads) into the anal submucosal or intersphincteric space may help to increase resting pressures by augmenting the anal cushions or restoring anal symmetry.

Operative management of anal incontinence is reserved for patients with frequent symptoms that have significant impact on a patient’s quality of life. For patients with incontinence resulting from obstetrical injury or previous anorectal surgery and evidence of an external anal sphincter defect on imaging, overlapping sphincteroplasty is an option. With the patient in the prone position, a curved incision parallel to the anus is made over the perineal body. The two ends of the sphincter muscle are identified and are mobilized laterally. In order to recreate the complete circle of the anal sphincter, the ends of the muscle are sutured in an overlapping fashion (Fig. 70-26). Short-term outcomes following sphincteroplasty are quite good, with up to 85% of patients reporting improvement, however, many patients report deterioration of function over time.³⁶

The artificial bowel sphincter (ABS) involves the placement of a cuff around the anal canal that generates external pressure to maintain tonic closure. This inflatable cuff is attached to a pressure-regulating reservoir placed in the retropubic space, and a control pump which is implanted into the labium majoris or scrotum (Fig. 70-27). When the patient feels the urge to defecate, the cuff is deflated for several minutes, thereby opening the anal canal to allow passage of stool. The complication rate of this procedure is quite high, with reports of explantation or revision of the device in almost half of all patients due to infection or malfunction, however the majority of patients with a functioning device report marked improvement in continence.³⁷ Although the ABS is no longer commercially available, the magnetic anal sphincter, now in trials in the USA, may allow for the significant benefits of the ABS without the very high rates of infection, extrusion, and explantation.

Figure 70-26. Overlapping sphincteroplasty. **A.** An anterior curvilinear incision is made over the perineal body, the scar is divided, and the edges of the external sphincter are grasped with Allis clamps. **B.** The external sphincter is dissected until the edges can be overlapped for several centimeters. **C and D.** An overlapping repair is performed with four mattress sutures.

Figure 70-27. Implanted silicone neosphincter. **A:** Female. **B:** Male.

Sacral nerve stimulation (SNS) involves the percutaneous placement of an electrode into the foramen of the sacral vertebrae, most commonly S3. SNS was initially used to treat urinary incontinence, however it was noted that patients with combined incontinence had improvement in fecal continence as well; the exact mechanism of action is unknown. Following lead placement under fluoroscopy, the patient undergoes a 2-week test period to assess the effect of stimulation. If continence is significantly improved, a permanent stimulator is implanted subcutaneously at a second operation. Durable 5-year

results have been reported, with 89% of patients reporting improvement and 36% reporting full continence.³⁸ SNS may be offered to patients both with and without evidence of sphincter defects. Tibial nerve stimulation has also been shown to lead to improvement in anal continence, however this therapy is currently not approved for use in the United States.³⁹

In patients with severe incontinence for whom alternative methods have failed, creation of a sigmoid colostomy may improve quality of life and allow them to resume normal daily activities.

Sexually Transmitted Diseases of the Anorectum

The annual incidence of sexually transmitted diseases is approximately 15 million cases in the United States. As anal erotic practices have increased, the incidence of sexually transmitted diseases of the anus and rectum has also increased. These are typically the result of anal receptive intercourse, but in some instances represent contiguous spread from genital infections.

Gonorrhea

Gonorrhea is caused by the gram-negative intracellular diplococcus *Neisseria gonorrhoeae*, with an incubation period that ranges from 3 days to 2 weeks. Symptomatic anorectal gonococcal infection results in pruritus or tenesmus, accompanied by a mucoid and sometimes bloody rectal discharge. Left untreated, a more advanced systemic infection can occur resulting in such conditions as endocarditis, pericarditis, and a unilateral migratory gonococcal arthritis of large joints.

Anorectal gonorrhea results in a thick yellow mucopurulent discharge from the anus. This purulent material is often able to be expressed from the anal crypts and can be visualized directly by applying gentle external pressure while viewing the distal anorectum through an anoscope. Sigmoidoscopy may reveal a proctitis extending to no more than about 10 cm from the anal verge. Although these findings may be mistaken for an ulcerative or nonspecific proctitis, abscesses, fistulae, and ulcers are not typical. Diagnosis is confirmed by culture on a Thayer–Martin medium plate incubated in a carbon dioxide environment.

Due to the increasing prevalence of penicillinase-producing *N. gonorrhoeae*, penicillin G is no longer recommended. First-line treatment is a single intramuscular injection of 250 mg of ceftriaxone. Alternative treatments that have been proposed include single oral dose of 500 mg of cefixime or a single oral dose of a fluoroquinolone. Because of the high rate of concomitant infection with Chlamydia, patients should be given appropriate treatment for Chlamydia as well. Sexual partners from the past 60 days should also be treated.

Chlamydia/Lymphogranuloma Venereum

Chlamydia trachomatis is the most common sexually transmitted bacterial infection worldwide. In the United States, male homosexuals account for the majority of rectal Chlamydial infections. With 15 known serotypes, anorectal Chlamydia infection can cause proctitis (serotypes D-K) or lymphogranuloma venereum (LGV) (serotypes L1–L3). Transmission of disease is through anoreceptive intercourse, with an incubation period ranging from 5 days to 2 weeks; secondary involvement can also occur as a late manifestation of genital infection.

Symptoms of non-LGV anorectal infection include rectal pain, tenesmus, and fever, although a substantial number of infected patients will be asymptomatic. Examination reveals enlarged matted inguinal lymph nodes and proctosigmoidoscopy shows an erythematous rectal mucosa without frank ulcerations. Patients with LGV also complain of pain, fever, and tenesmus but often have a slight mucopurulent discharge and hematochezia. The inguinal lymph nodes in LGV are often more enlarged as they fuse into a large indurated mass with overlying erythema. Evaluation of the rectal mucosa reveals a more severe granular proctitis with mucosal friability and frank ulceration. Left untreated, the disease may progress to fistulae, abscesses, and late rectal strictures. In this setting, LGV may be confused for perianal Crohn's disease, however the marked inguinal lymphadenopathy may help distinguish LGV from Crohn's.

Treatment of Chlamydia infection is with a single oral dose of azithromycin (1 g) or doxycycline (100 mg) twice a day for 7 days. Alternative therapy includes erythromycin or a fluoroquinolone. Treatment of LGV is a 21-day course of either erythromycin or doxycycline. Sexual partners also require treatment to prevent reinfection.

Herpes Simplex Virus

Herpes is the most prevalent sexually transmitted disease in the United States where it is estimated that 20% of the general population are affected. The majority of anorectal herpes infections are caused by

HSV-2 with only about 10% being caused by HSV-1. Transmission is through autoinoculation or direct contact with an infected individual who is shedding the virus, and the clinical infection may begin 4 to 21 days following anoreceptive intercourse. Patients present with small red vesicles which may be clustered or scattered in the perianal skin, anal canal or perineum, are extremely painful to touch. Proctoscopy reveals friable mucosa, ulceration, and the mucopurulent discharge. These findings will be limited to the distal 10 cm on proctoscopy. Tender inguinal adenopathy occurs in up to 50% of patients with HSV proctitis. Recurrent attacks are generally milder and shorter in duration.

Diagnosis is made on clinical examination, finding multinucleated giant cells with intranuclear inclusion bodies on Pap smear, a positive Tzank preparation or a positive culture. As the acute infection is self-limited, treatment includes warm sitz baths and oral analgesics. The use of antiviral medications has been shown to shorten the length of symptoms, but does not affect recurrence rates. Acyclovir (400 mg five times/day for 10 days) is most commonly used for initial infection. Recurrent attacks may be treated with acyclovir (200 mg five times/day) or valacyclovir (500 mg twice/day). Suppressive antiviral therapy may be considered in patients who have more than five attacks per year.

Condyloma Acuminata

7 Anal condylomata acuminata or “warts” are caused by the human papilloma virus (HPV). HPV is a papovirus, and more than 80 subtypes of HPV have been identified. Serotypes 6 and 11 are most commonly associated with the benign, exophytic condylomata of the anogenital region. Serotypes 16 and 18 have been associated with more aggressive lesions that can progress to invasive squamous cell cancers.

The primary mode of transmission of anogenital HPV is sexual intercourse. Inoculation of the anal epithelium allows entry of the HPV into the basal cell layers. As these cells proliferate viral replication occurs in the nucleus. The basal cells then migrate toward the surface and infective particles are released in the form of visible warts. Mature infectious particles are found in the surface layers of these lesions.

Condyloma acuminata are easily recognized as epithelialized cauliflower-like projections. They may be flat, raised, sessile or pedunculated, and range in size from millimeters to a large fungating lesions known as giant condyloma acuminatum (Buschke–Lowenstein). They may be in clusters or grow to cover the perineum and anal canal in a “carpet-like” fashion. The warts may be asymptomatic or may cause pruritus, bleeding, or discharge. Anoscopy is important in evaluating for lesions within the anal canal.

The goal of treatment is removal of all gross disease while minimizing morbidity, although this does not ensure eradication of infection. Tangential excision, cryotherapy, or fulguration of small lesions with local anesthesia can be performed as an office procedure with little discomfort to the patient. Larger lesions are treated by excision in the operating room, while electrodesiccation is performed of any remaining smaller condyloma.

Topical agents such as podofilox and imiquimod can be applied by the patient, but neither is approved for use in the anal canal. Imiquimod is an immune response modifier that increases local production of interferon. Complete response can be expected in 50% of patients treated with imiquimod, with 11% of patients experiencing a recurrence. It can be used as initial treatment with electrodesiccation reserved for those who have incomplete response, or following destructive treatment and epithelial healing to treat remaining or recurrent disease.⁴⁰

Anal Intraepithelial Neoplasia

The role of HPV in the development of cervical cancer in females has been clearly established, however its significance in the development of anal cancer is not as well defined. Serotypes 16 and 18 have a higher propensity to initiate the development of carcinoma, and have a predilection for the less stable epithelium of the upper anal canal transition zone rather than the modified skin of the lower anal canal anoderm. They may, however, be identified in the anal skin margin as well.

The incidence of anal cancer in HIV-positive homosexual males is estimated to be 38 times that of the general population and twice the risk in HIV-negative homosexual males.⁴¹ HPV infection has been reported in 93% of HIV-positive homosexual males compared with 60% of HIV-negative homosexual males.⁴² Anal intraepithelial neoplasia (AIN), a precursor to the development of anal cancer, also has a markedly increased incidence in HIV-positive individuals. It is felt that as HIV disease has become a chronic, manageable condition, patients are living long enough to progress from AIN to anal cancer. Some have therefore recommended screening and surveillance programs similar to those for cervical cancer.

Anal cytology has been described as a screening tool to detect abnormal cells in high-risk patients. Those who are found to have abnormal Papanicolaou smears undergo high-resolution anoscopy with acetowhitening and staining with Lugol solution and biopsy of any suspicious lesions. Options for treatment include local destruction (cryotherapy or fulguration), excision, or observation.

AIN is graded on the degree of dysplasia. Low-grade AIN (grade I) rarely undergoes malignant transformation, and can be observed or ablated if symptomatic. High-grade AIN (grades II and III) is believed to be the premalignant counterpart of anal squamous cell cancer, however the incidence and predictability of the progression of AIN to invasive cancer is unclear. Some authors recommend aggressive destruction or excision of any high-grade lesions, however there is currently no evidence that removal of high-grade AIN results in a reduction of the risk of anal cancer. Others have therefore instead recommended that AIN be observed unless there are gross visible lesions or ulcerations present.

HIV and AIDS

Surgery for anorectal diseases is the most common indication for surgery in HIV-infected patients and in 5% of patients their anorectal complaint is the presenting symptom of their HIV infection. Several studies demonstrated poor wound healing and increased morbidity in the surgical treatment of anorectal disease in AIDS patients. Delayed or failed wound healing has been associated with presence of AIDS, absolute leukocyte count, and CD4 count.

Anal fissures that occur in the HIV-positive patient must be distinguished from idiopathic AIDS-related anal ulcers and ulcerating sexually transmitted diseases such as HSV or syphilis. Anal fissures in this patient population are indistinguishable from those in the general population and their treatment is similar – initial conservative management with surgery for treatment failures. Treatment of fissure in HIV-positive patients also includes controlling diarrhea when possible and encouraging abstinence from anoreceptive intercourse.

With the increasing use of highly active antiretroviral therapy (HAART), the incidence of AIDS-related anorectal ulcers has decreased markedly, however they are still found in patients with low CD4 counts. AIDS-related ulcers typically occur more proximal in the anal canal (frequently above the dentate line), are broad based with deep ulceration with destruction sphincter planes, and may demonstrate mucosal bridging. Surgical debridement allows for adequate drainage of feculent or purulent material trapped in the ulcer and removes necrotic debris. The area should also be biopsied to rule out malignancy. Intralesional injection with steroids has also been described to decrease pain, however it has not been demonstrated to affect healing. Perianal suppurative diseases are common conditions in AIDS patients. Abscesses should be drained using small incisions, and judicious use of draining setons will help lessen recurrent sepsis. The abscess should also be cultured and broad-spectrum antibiotics should be given.

Kaposi sarcoma, which is associated with the herpesvirus HHV-8, is one of the more common malignancies in AIDS patients. Found more commonly in patients with low CD4 counts, its incidence has decreased in the era of HAART therapy. Kaposi sarcoma may occur in the colon or rectum, but may also be found in the anal canal and perianal skin. Most patients are asymptomatic, however bleeding or obstruction may rarely occur. Treatment is directed at improving the patient's CD4 count, however radiation and chemotherapy have also been employed.

Symptomatic cytomegalovirus (CMV) infection may also occur in profoundly immunocompromised AIDS patients. CMV can cause proctocolitis that presents with diarrhea, fever, and abdominal pain. Examination of the mucosa of the rectum demonstrated sharply demarcated shallow ulcers with fibrinous exudate. Biopsies that demonstrate “owl's eye” inclusion bodies are diagnostic. Treatment is with antiviral medications and initiation of HAART therapy.

NEOPLASTIC ANORECTAL DISEASE

Neoplasms of the anal region are relatively rare, and include both benign and malignant tumors. Important in the diagnosis and management of these conditions is defining the location of the tumor with reference to landmarks such as the dentate line and anal verge because treatment of tumors of the anal canal is often significantly different from treatment of tumors of the anal margin. The American Joint Commission on Cancer has developed standardized terminology and has recognized the anal verge as the line dividing between the anal canal and anal margin. Although it may be difficult to determine the exact location of large, bulky tumors that encompass both the anal canal and anal verge, the location of most tumors of the anal margin can be determined with inspection alone.

Anal Margin Tumors

Bowen Disease (High-Grade AIN)

Although AIN is more common in HIV-positive individuals, high-grade AIN may develop in the perianal skin of HIV-negative patients. Also referred to as Bowen disease, these lesions tend to grow slowly, and are more prevalent in older women and immunosuppressed patients.⁴³ While perianal Bowen disease is often asymptomatic, patients may present with burning or pruritus. Changes seen on examination may range from thickened erythematous skin to discrete scaly or crusted plaques, often making it difficult to differentiate from other disorders such as psoriasis or eczema. Biopsy of any atypical anal lesions is mandatory (Fig. 70-28).

While wide local excision has traditionally been the treatment of choice for Bowen disease, the understanding that the disease is likely related to HPV infection has changed the treatment paradigm. Excision should be performed in any patient with intractable itching or burning, those with an atypical lesion or a lesion than 3 cm, or when biopsy demonstrates invasive squamous cell cancer. Mapping of the perianal skin with circumferential biopsies will often show residual disease, and evidence that this practice improves patient outcomes is lacking. As in patients with HIV and AIN, the role of high-resolution anoscopy with staining of the perianal skin remains controversial. Although Bowen disease is a premalignant condition, the rate of malignant transformation in the HIV-negative population is likely lower than in HIV-positive patients with high-grade AIN. Patients with asymptomatic disease may therefore be closely observed, with target biopsy of any suspicious areas.

Squamous Cell Carcinoma

8 Squamous cell carcinomas (SCCs) located at the anal margin are similar to those that develop elsewhere in skin. The disease afflicts men and women at an equal rate and tends to present in the seventh decade of life. Patients often present with a mass, pruritus, rectal pain, or bleeding, and the gross appearance is typically a mass with central ulceration and rolled, everted edges. While symptoms may mimic other conditions such as fistula, hemorrhoids, or chronic pruritus, any chronic unhealed or indurated ulceration in the perianal area should be biopsied (Fig. 70-29). Due to its location, the diagnosis of perianal squamous cell cancer is often delayed, with more than 50% of cases diagnosed more than 24 months after the onset of symptoms.⁴⁴

Treatment of superficial squamous cell cancer of the anal margin that does not invade muscle is local excision with a 1-cm margin. Radiation or chemoradiation should be considered for large tumors invading the sphincter and/or radical resection with abdominoperineal resection is another option, however this procedure has been associated with high failure rates from local recurrence, inguinal lymph node metastasis, and distant metastasis.⁴⁵ The prognosis for patients with T1 tumors (those <2 cm) is excellent, with 5-year survival rates approaching 100%. Five-year survival of patients with larger tumors is variable, depending on the type of treatment.

Figure 70-29. Chronic unhealed or indurated ulceration in the perianal area. Courtesy of Dr. Scott Steele.

Paget Disease

Paget disease is an intraepithelial adenocarcinoma of the perianal skin. While this disease was initially described in the breast, it may also occur in the axilla and anogenital region. The exact origin of Paget cells is unknown, however authors have hypothesized that they arise from apocrine or sweat glands, or are metastatic from an underlying adenocarcinoma. Perianal Paget disease begins as a benign in situ neoplasm but may eventually become invasive as an adenocarcinoma.

Paget disease is rare disease, and occurs most commonly in elderly patients. The typical appearance is an erythematous, sometimes sharply demarcated rash that may ooze or scale. Paget disease must be differentiated from other dermatologic conditions such as eczema, lichen sclerosis, and hyperkeratosis; these conditions tend to present in a circumferential pattern, whereas Paget disease tends to be unilateral. The diagnosis is made by biopsy, which demonstrates the presence of periodic acid–Schiff positive Paget cells (Fig. 70-30). Patients with Paget disease should also undergo a colonoscopy, as synchronous visceral carcinomas have been found in up to 50% of patients.⁴⁶

The treatment of perianal Paget disease in the absence of invasive carcinoma is wide local excision. Because the disease may extend beyond the grossly visible margin, mapping biopsies at least 1 cm from the edge of the lesion in all four quadrants is recommended. Small lesions may be resected with the wound left open, however if extensive resection is required, reconstruction may be performed with advancement or rotational flaps.⁴⁷

Patients with perianal Paget disease and concomitant rectal adenocarcinoma should undergo abdominoperineal resection, whereas those with anal cancer should be treated with chemotherapy and radiation. Patients with invasive Paget disease should undergo APR, however the prognosis is quite poor as the majority of patients have distant metastases at the time of diagnosis.⁴⁸ The pattern of metastasis is similar to that of adenocarcinomas of the distal rectum.

Basal Cell Carcinoma

Basal cell carcinomas of the perianal skin are rare. Similar to basal cell cancers of the skin elsewhere on the body, these tumors typically appear as an ulcer with irregular and raised edges. This condition is more common in men than women, and one-third of patients have basal cell cancers on other cutaneous sites.⁴⁹ Treatment is wide local excision followed by close surveillance, as recurrence is not uncommon.

Figure 70-30. Perianal Paget disease. Paget cells are above the basal layer.

Figure 70-31. Epidermoid cancer of the anal canal. Courtesy of Dr. Mariana Berho.

Anal Canal Tumors

Epidermoid or Squamous Cell Carcinoma

Cancers that arise within the anal canal differ in treatment and prognosis from tumors that occur in the perianal skin. Epidermoid cancer of the anal canal has various microscopic appearances, including squamous cell (large cell keratinizing), transitional zone (large cell nonkeratinizing), basaloid, or mucoepidermoid epithelium ([Fig. 70-31](#)). The term cloacogenic carcinoma has also been used for basaloid and transitional carcinomas. The clinical presentation, treatment, and prognosis are similar among the different forms of epidermoid carcinomas.

Patients with anal canal tumors typically present with bleeding and pruritus. As with anal margin tumors, these symptoms are often initially misdiagnosed as hemorrhoids or fissure. Digital examination of the anal canal will often demonstrate an indurated mass. Anoscopy allows for visualization of the tumor and biopsy to confirm the diagnosis. Physical examination should also include palpation of the inguinal region to evaluate for enlarged lymph nodes. Although there is no association between epidermoid anal cancer and colorectal cancer, most clinicians recommend a colonoscopy to evaluate the colon and rectum.

Staging of squamous cell cancer of the anal canal is based on the size of the primary tumor and evidence of lymph node and distant metastases and is detailed in [Table 70-6](#). Although endoanal ultrasound may demonstrate the depth of invasion and enlarged perirectal lymph nodes, these variables are not part of the TNM staging system. Enlarged or suspicious groin lymph nodes should be biopsied, either by excision or fine-needle aspiration. Computed tomography of the abdomen and pelvis is indicated to detect for distant metastatic disease. PET scanning is not typically done as part of the initial staging, however it may be useful in assessing persistent or recurrent disease after treatment. HIV testing should be considered in those patients who are at higher risk.

Prior to 1975, the treatment of anal canal squamous cell cancer included surgery alone or radiation therapy alone. Early-stage lesions were treated by local excision while patients with more advanced tumors underwent abdominoperineal resection. Local recurrence rates approached 50% and 5-year

survival was 40% to 70%.⁵⁰ Nigro et al. treated patients with preoperative chemotherapy and radiation prior to APR in an effort to decrease recurrence rates and discovered that the majority of these tumors had completely regressed at the time of surgery. This finding led them to recommend treatment with chemoradiation alone with surgery reserved for patients with residual disease, commonly referred to as the Nigro Protocol. This regimen includes external beam radiation to the primary carcinoma as well as the pelvic and inguinal lymph nodes, combined with intravenous 5-fluorouracil and mitomycin C. A typical modified Nigro regimen is summarized in Table 70-7. Since the initial report, multiple studies have confirmed these results, including two randomized trials.^{51,52}

Patients who are treated with chemoradiation should be followed closely to detect any evidence of recurrence. This includes physical examination and anoscopy with biopsy of any suspicious areas. In patients with persistent or recurrent disease, abdominoperineal resection is recommended. Studies of patients who underwent salvage APR show better survival in recurrent rather than persistent disease, with a 57% 5-year survival rate.⁵³ Inguinal node metastasis at initial presentation prior to treatment with chemoradiation is also associated with poor outcome after APR for treatment failure.⁵⁴ It is important to consider that perineal wound complication rates are high in patients who undergo APR for recurrent anal cancer after treatment with chemoradiation,⁵⁵ and reconstruction with a rectus abdominis myocutaneous flap should be considered. Radical groin dissection may also be considered in patients with symptomatic inguinal disease after chemoradiation.

Adenocarcinoma

Anal canal adenocarcinomas are relatively rare, accounting for less than 10% of all anal carcinomas.⁵⁶ Their presentation is similar to squamous cell cancers of the anal canal, with pain, bleeding, pruritus, and a palpable mass, although these tumors tend to have a more aggressive natural history than SCC. These tumors tend to present in the seventh decade of life and occur equally in males and females.⁵⁷

Adenocarcinomas of the anal canal are classified according to their cell of origin. Rectal-type adenocarcinomas arise from the transitional zone in the upper anal canal and are indistinguishable from adenocarcinoma of the distal rectum. These tumors are treated in a similar manner as rectal cancer, with chemoradiation followed by abdominoperineal resection; local excision may be an option in small, early stage tumors that do not invade the anal sphincter complex. Anal gland-type adenocarcinomas arise from the mucin-secreting goblet cells that line the glands within the anal canal. These tumors may develop in an extramucosal manner without involvement of the anal canal epithelium. There have also been reports of mucinous adenocarcinoma developing in the setting of a chronic anal fistula, although the likely origin of these tumors is also the goblet cells within the anal glands. Anal gland-type adenocarcinomas have a lower response rate to chemoradiation than SCC of the anal canal, and these tumors are therefore best treated with combined chemoradiation and abdominoperineal resection.

Melanoma

Melanoma occurs most commonly in the skin and eyes, but can also develop from the transitional epithelium within the anal canal or the anoderm at the anal verge. This tumor is more common in females than in males and is relatively rare, accounting for less than 1% of all anal malignancies. Symptoms are typically pain, pruritus, and bleeding. Most lesions are pigmented, and may frequently be incorrectly diagnosed as a thrombosed hemorrhoid. Some anal melanomas may not contain pigment and can be difficult to differentiate from SCC.

Anal canal melanomas spread submucosally into the rectum, but do not typically invade other organs. Lymphatic spread to mesenteric lymph nodes is present in up to 35% of patients at the time of diagnosis,⁵⁸ and hematogenous spread to distant sites is common as well. Melanomas of the anal canal do not respond to chemotherapy or radiation, making surgery the only chance for cure. Options include wide local excision or abdominoperineal resection, however the prognosis is extremely poor, with 5-year survival rates of less than 30%.⁵⁹ While APR may help to reduce local recurrence, survival rates do not differ from wide local excision and most authors therefore advocate for local excision to avoid the morbidity of a permanent colostomy.⁶⁰

STAGING AND CLASSIFICATION

Table 70-6 American Joint Committee on Cancer Staging Classification for Squamous Cell Carcinoma of the Anal Canal

Primary Tumor (T)	
Tx:	Primary tumor cannot be assessed
T0:	No evidence of primary tumor
Tis:	Carcinoma in situ
T1:	Tumor 2 cm or less in greatest dimension
T2:	Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3:	Tumor more than 5 cm in greatest dimension
T4:	Tumor of any size invades adjacent organ(s), e.g., vagina, urethra, bladder (involvement of sphincter muscle alone is not classified as T4)
Regional Lymph Nodes (N)	
Nx:	Regional lymph nodes cannot be assessed
N0:	No regional lymph node metastasis
N1:	Metastasis in perirectal lymph node(s)
N2:	Metastasis in unilateral internal iliac and/or inguinal lymph nodes
N3:	Metastasis in perirectal and inguinal lymph nodes and/or bilateral internal iliac and/or inguinal lymph nodes
Distant Metastasis (M)	
Mx:	Distant metastasis cannot be assessed
M0:	No distant metastasis
M1:	Distant metastasis
Stage Grouping	
Stage 0	Tis, N0, M0
Stage I	T1, N0, M0
Stage II	T2, N0, M0 T3, N0, M0
Stage IIIA	T1, N1, M0 T2, N1, M0 T3, N1, M0 T4, N0, M0
Stage IIIB	T4, N1, M0 Any T, N2, M0 Any T, N3, M0
Stage IV	Any T, Any N, M

TREATMENT

Table 70-7 Modified Nigro Regimen for Squamous Cell Carcinoma of the Anal Canal

Treatment	Dose	Schedule
External radiation	50 Gy, to the primary carcinoma and 35–45 Gy to pelvic inguinal nodes	Start day 1 (2 Gy/d, 5 d/wk for 5 wk)
Systemic chemotherapy	Fluorouracil, 1,000 mg/m ² /24 h as a continuous infusion for 4 d	Start day 1; repeat 4-d infusion starting day 28
Mitomycin C	10–15 mg/m ² as intravenous bolus	Day 1 only

Chapter 71

Diseases of Appendix

Edward A. Levine and Nathan Mowery

Key Points

- 1 The anatomy of the appendix tells the story of the epidemiology of appendicitis and can serve as a road map for its intra-abdominal location.
 - 2 Despite advances in diagnostic tests, appendicitis remains a clinical diagnosis.
 - 3 When indicated helical CT with IV contrast is the test of choice when imaging is indicated in patients with suspected appendicitis.
 - 4 In selected patients with acute, uncomplicated appendicitis, antibiotic treatment is an appropriate alternative to appendectomy.
 - 5 The decision to perform an interval appendectomy following successful nonoperative management with antibiotics and percutaneous drainage remains controversial.
 - 6 Laparoscopic appendectomy confers many benefits over open appendectomy, and should be strongly considered as the preferred approach where surgical expertise is appropriate and equipment is available and affordable.
 - 7 Outpatient appendectomy should be considered in cases of uncomplicated appendicitis.
 - 8 Appendiceal cancer represents approximately 1% of colon malignancies.
 - 9 Appendiceal cancer typically presents as unexpected finding on final pathology after appendectomy for presumed acute appendicitis.
 - 10 Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy (HIPEC) is a standard approach for appendiceal cancer with peritoneal dissemination.
-

APPENDICITIS

The first description of appendicitis in the literature was by Lorenz Heister in 1711.¹ He described a perforated appendix with associated abscess in the autopsy report of a prisoner. Unfortunately, autopsy was the most common operation done for appendicitis until 1827, when a French surgeon, Francois Melier, suggested removing the appendix during episodes of right lower-quadrant pain.¹ It was not until advances in anesthesia and antisepsis developed in the late 1800s that appendectomy became more common.

Perhaps the most famous case of appendicitis is that of King Edward VII, the first son of Queen Victoria. After a prolonged period waiting to inherit the crown from his mother, Edward, was set to become King of England. Less than 2 weeks before the coronation, the future king developed abdominal discomfort. A staff of physicians attended to Edward including two prominent British surgeons, Lord Joseph Lister and Sir Frederic Treves. They observed right lower-quadrant swelling, tenderness, and fever in the future king. The medical staff was unanimous in recommending an operation, but Edward was hesitant on the eve of his coronation. It fell to Lister to persuade Edward that an urgent operation was necessary. Westminster Abbey not only hosted coronations but also funerals of British royalty. Edward responded to his medical staff, “I must keep faith with my people and go to the [Westminster] Abbey for the coronation.” Edward was adamant, and after hearing him repeat “I must go to the Abbey,” Treves replied, “Then, Sir, you will go as a corpse.”

Edward finally consented to surgery, and on June 24, 1902, Treves operated on Edward at Buckingham Palace. He opened a large periappendiceal abscess, evacuated pus, and left two large drains in place. He did not remove the appendix. The wound was packed open and the entire procedure took approximately 40 minutes. Edward recovered successfully and underwent coronation approximately 7 weeks after surgery. He served as king for the remaining eight years of his life without ever undergoing an interval appendectomy.

ANATOMY

- 1 The anatomy of the appendix tells the story of the epidemiology of appendicitis. Embryologically, the appendix is part of the cecum from which it originates where the three tenia coli coalesce on the cecum. Not surprisingly, the appendix resembles the cecum histologically and includes circular and longitudinal muscle layers. In addition, the appendix contains an abundance of lymph follicles in the submucosa, numbering approximately 200. The highest number of lymph follicles occurs in the 10- to 20-year-old age group, with a decline in number after age 30; lymph follicles are typically absent after age 60.

The appendix arises from the cecum approximately 2.5 cm below the ileocecal valve. It varies in length from complete agenesis to more than 30 cm, but it is usually 5 to 10 cm in length. The mean width is 0.5 to 1.0 cm. The various positions of the appendix are conveniently categorized into the following locations: paracolic (the appendix lies in the right paracolic gutter lateral to the cecum), retrocecal (the appendix lies posterior to the cecum and may be partially or totally extraperitoneal), preileal (the appendix is anterior to the terminal ileum), postileal (the appendix is posterior to the ileum), promontoric (the tip of the appendix lies in the vicinity of the sacral promontory), pelvic (the tip of the appendix lies in or toward the pelvis), and subcecal (the appendix lies inferior to the cecum). Wakeley² performed a postmortem analysis of 10,000 cases and described the frequency of the location of the appendix as follows: retrocecal, 65.3%; pelvic, 31%; subcecal, 2.3%; preileal, 1%; and right paracolic and postileal, 0.4%. In essence, the appendix may lie in multiple locations, essentially at virtually any position in a clockwise rotation from the base of the cecum. The clinician must appreciate that the anatomic location of the appendix determines the presentation of symptoms and signs during an episode of appendicitis.

PATHOPHYSIOLOGY

Wangensteen and Dennis³ demonstrated experimentally that luminal obstruction leads to the development of acute appendicitis. The appendix has a small luminal diameter in relation to its length. Conventional wisdom holds that this configuration predisposes the appendix to closed-loop obstruction and subsequent inflammation. Specifically, proximal obstruction (by any number of initiating factors) leads to ongoing mucous secretion of the appendiceal mucosa distal to the obstruction into a closed lumen with elevation of intraluminal pressure. Rapid distention of the appendix ensues because of its small luminal capacity and intraluminal pressures can reach 50 to 65 mm Hg. Distension of the appendix stimulates visceral afferent pain fibers, producing a somewhat vague and diffuse periumbilical pain. Distention of the appendix often causes reflex nausea and/or vomiting with a progressive increase in the severity of the visceral pain.

As luminal pressure increases, venous pressure is exceeded and mucosal ischemia develops. Once luminal pressure exceeds 85 mm Hg, thrombosis of the venules that drain the appendix occurs and, in the setting of continued arteriolar inflow, vascular congestion and engorgement of the appendix become manifest. With vascular congestion, the appendiceal mucosa becomes hypoxic and begins to ulcerate, resulting in compromise of the mucosal barrier, and leading to invasion of the appendiceal wall by intraluminal bacteria. This sets in motion an inflammatory process that leads to mucosal disruption followed by serosal involvement and finally inflammation of the nearby parietal peritoneum, resulting in the characteristic shift in location of pain to the right lower quadrant along with localized tenderness. If unimpeded, luminal pressure rises to a level that induces venous infarction, full-thickness necrosis, and perforation. The length of time required for the disease to progress to gangrene and perforation is highly variable. One study demonstrated a mean duration of abdominal pain of 46.2 hours in patients with gangrene and 70.9 hours for perforation.⁴

Fecal stasis and fecaliths are the most common cause of appendiceal obstruction, followed by lymphoid hyperplasia, vegetable matter and fruit seeds, inspissated barium from previous radiographic studies, intestinal worms (especially ascarids), and tumors (such as carcinoid). It is important to note that the offending agent causing obstruction is only found in 50% of the cases. Accordingly, it is fair to state that luminal obstruction appears to account for many cases of appendicitis, but the cause for a substantial number of cases remains elusive.

DIAGNOSIS OF ACUTE APPENDICITIS

Despite knowing about the disease process for over 300 years, identifying which patients have it still poses a significant challenge today. In the United States, approximately 11 of 10,000 people will develop acute appendicitis over their lifetime, with the typical age of onset between the ages of 11 and 19 years.⁵ Appendicitis is a common problem; there are more than 300,000 hospital discharges for appendicitis in the United States per year. Due to its frequent epidemiology it is often thought of as a straightforward diagnosis, but this is rarely the case. Diagnostic errors are common, with overdiagnosis leading to negative appendectomies, and with delays in diagnosis leading to perforations. The misdiagnosis of appendicitis has significant economic ramifications; in a nationwide study of administrative data, a negative appendectomy rate of 15% resulted in more than \$740 million in hospital charges.⁶ On the other end of the spectrum, delay or error in diagnosis of acute appendicitis is now one of the most frequent allegations of medical malpractice that are leveled against general surgeons, emergency medicine physicians, and primary care physicians.

As with any patient presenting with abdominal pain the evaluation should begin with a thorough history and physical examination. In certain populations, appendicitis remains one of the disease processes cared for by surgeons that can be diagnosed with a careful history and physical examination alone, sparing the patient the cost and discomfort of imaging. Published guidelines note that the combination of clinical and laboratory findings of characteristic abdominal pain, localized tenderness, and laboratory evidence of inflammation will identify most patients with suspected appendicitis.⁷ Other diagnostic strategies may include radiologic imaging or the use of scoring systems with or without computer support. Ultimately, the “gold standard” for a positive diagnosis is the histopathologic confirmation of appendicitis, although standard criteria are lacking.

HISTORY AND PHYSICAL EXAMINATION

2 Despite advances in diagnostic tests, appendicitis remains a clinical diagnosis. Clinical symptoms elicited by the history may include fever, nausea, vomiting, anorexia, migration of pain to the right lower quadrant, and aggravation of pain by movement. Physical examination may reveal signs of peritoneal irritation in the right lower quadrant or diffusely. Rectal examination may reveal tenderness. There is evidence that the order that the symptoms present in is often diagnostic. Authors have suggested that pain usually comes before nausea or fever and if the order is reversed then the diagnosis is not appendicitis. Furthermore, there are a variety of named signs that may be associated with appendicitis depending upon the location of the inflamed appendix ([Table 71-1](#)). The signs and symptoms are common and nonspecific; each individual sign and symptom is only weakly predictive of appendicitis.⁸ Furthermore, the differential diagnosis for right lower-quadrant abdominal pain is wide and varies with age and gender. When signs and symptoms were compared between children and adults, they were similarly predictive of appendicitis, with the exception of right lower-quadrant pain which had a much higher likelihood ratio in adults than in children.^{9,10} Another limitation of relying on clinical findings alone is that elicitation of physical signs is subjective; multiple studies have demonstrated poor interrater reliability between trainees and attending physicians, as well as between subspecialists.^{11,12} However, when used in combination with laboratory values, the diagnostic utility of clinical findings increases significantly.

LABORATORY VALUES

Laboratory values that have been associated with acute appendicitis include leukocytosis, left shift, and elevated markers of inflammation such as C-reactive protein (CRP) and erythrocyte sedimentation rate.^{8,10} As with the clinical symptoms and signs, each individual laboratory test value is only weakly discriminatory and predictive of acute appendicitis.⁸ However, combinations of clinical findings and laboratory values or combinations of multiple laboratory values are more accurate and predictive.⁸ A meta-analysis revealed that the greatest discriminators and predictors of acute appendicitis included a history of migration of pain, clinical findings of peritoneal irritation, and laboratory values reflecting an inflammatory response (i.e., CRP).⁸

Table 71-1 Named Clinical Signs Associated With Appendicitis

Dunphy sign	Increased right lower-quadrant pain with coughing
Obturator sign	Increased pain with flexion and internal rotation of the hip
Psoas sign	Increased pain with passive extension of the right hip (can be elicited with the patient lying on the left side)
Rovsing sign	Increased right lower-quadrant pain during palpation in the left lower quadrant

Table 71-2 Alvarado or MANTRELS Scoring System

	Variable	Value
Symptoms	Migration	1
	Anorexia	1
	Nausea–vomiting	1
Signs	Tenderness in right lower quadrant	2
	Rebound of pain	1
	Elevation of temperature (>37.3°C)	1
Laboratory	Leukocytosis (WBC <10,000/uL)	2
	Shift to the left (>75% neutrophils)	1
Total Score		10

There have been numerous studies evaluating other potential serum and urinary markers of appendicitis, including but not limited to inflammatory cytokines such as serum interleukin-6, interleukin-8, and tumor necrosis factor alpha; serum neutrophil proteins such as lactoferrin and calprotectin; and urinary markers such as leucine-rich α -2-glycoprotein. None of these have been shown to be superior to traditional markers of inflammation in a prospective trial.

There are several clinical scoring systems that have been used in the diagnosis of acute appendicitis. The most common is the Alvarado scoring system published in 1986, also referred to as MANTRELS based on the mnemonic for remembering the combination of eight signs and symptoms (Table 71-2).¹³ The score ranges from 0 to 10; a patient with a score of 5 or 6 is typically observed, whereas a patient with a score of 7 or greater should undergo operation.¹³ Since then, there have been several studies evaluating the diagnostic accuracy of the Alvarado score, as well as modified versions of the Alvarado score such as the Pediatric Appendicitis Score,¹⁴ and other scores such as the Kharbanda¹⁵ and Lintula¹⁶ scores. In general, these clinical scoring systems have better predictive ability than individual symptoms or signs alone. However, these scoring systems do not have sufficient discriminatory or predictive ability to routinely be used alone to diagnose appendicitis. They have been used to determine the need for further radiologic studies¹⁷ or as a guide for dictating clinical management.¹⁸

RADIOLOGIC IMAGING

At one time, surgical clinical acumen was graded on the ability to diagnose appendicitis on physical examination, but currently, more and more patients are diagnosed using imaging studies. Population-based analyses of regional administrative data in the 1980s and 1990s demonstrated a significant increase in the use of ultrasound (US) and computed tomography (CT). One would hope that this increase in imaging would lead to a decrease in the number of ruptured or negative appendectomies, but that is not the case.^{19,20} On one hand, imaging may be helpful in the evaluation of patients with abdominal pain for excluding other diagnoses or for preventing unnecessary operations.¹⁹ On the other hand, imaging could potentially delay operative intervention, and in the case of CT, radiologic imaging exposes patients to the risks of ionizing radiation. Ultrasonography does not expose patients to ionizing radiation but is more operator dependent. In a meta-analysis of US and CT in children and adults, both US and CT were highly specific (93% to 95%) in children and adults, whereas CT was more sensitive than US.²¹

3 The Surgical Infection Society and Infectious Disease Society of America guidelines recommend helical CT with IV contrast as the test of choice when imaging is indicated in patients with suspected appendicitis. There is moderate supporting evidence for this from well-designed but nonrandomized trials.^{7,22} A recent meta-analysis evaluated the effect of CT on negative appendectomies, rates of perforation, and time to surgery in patients with acute right lower-quadrant pain.²³ The meta-analysis

concluded that preoperative CT resulted in a reduced rate of negative appendectomies but an increase in time to surgery, although there was no increase in rate of perforation. There are some data to support the use of noncontrast CT of the abdomen in adults. The test had reasonably high sensitivity and specificity for clinical decision making (93% and 96%, respectively).²⁴

There have been only a few randomized trials evaluating different strategies incorporating radiologic imaging on clinical outcomes. Only one trial found a difference in accuracy. Lee and colleagues compared a strategy of mandatory or selective CT scanning in patients with suspected appendicitis and less than 72 hours of symptoms. They found there were fewer negative appendectomies and perforations in the group undergoing mandatory scans.²⁵ Another trial reported that CT scanning changed management in only 26% of patients.²⁶

Clearly, CT can be useful for cases without clear indications for surgery.

IDENTIFYING PERFORATED APPENDICITIS PREOPERATIVELY

Distinguishing whether or not a patient is likely to have perforated or nonperforated appendicitis preoperatively may be helpful in terms of counseling the patient about alternatives for management (i.e., early vs. delayed appendectomy), risk for complications, and the expected postoperative course. A recent meta-analysis identified four studies that presented data for perforated appendicitis. Based on these studies, high values of laboratory markers of inflammation such as a WBC and granulocyte count and the CRP level were relatively strong predictors of perforated appendicitis, whereas low values were relatively strong predictors of not having perforated appendicitis.⁸ A combination of clinical finding and laboratory values can help identify ruptured appendicitis preoperatively by developing a scoring system for children based on five variables, including components of history, physical examination, laboratory values, and CT findings.²⁷ When the scoring system was applied to the study patient population, it increased the specificity of the pediatric surgeon's preoperative assessment from 83% to 98%.²⁷

FUTURE DIRECTIONS IN DIAGNOSIS

Research is ongoing to identify accurate, efficient, and cost-effective methods of diagnosis. Advances have included using molecular techniques for profiling gene and protein expression to identify novel markers for appendicitis.^{28–30} Imaging alternatives to CT scans such as bedside surgeon-performed US,³¹ magnetic resonance imaging,³² or low-radiation CT scanning³³ are being investigated in terms of their diagnostic accuracy and their potential to reduce exposure to radiation. Another avenue of investigation is the use of machine learning and advanced statistical models for informing decision making.³⁴ As advances in technology and diagnostic strategies are made, any improvements in accuracy must be balanced against the proven utility of bedside clinical evaluation as well as costs and potential harms.

Figure 71-1. Acute suppurative appendicitis.

MANAGEMENT

Background for Nonoperative Management for Acute Uncomplicated Appendicitis

Appendectomy for acute appendicitis is one of the most common surgical procedures performed worldwide (Fig. 71-1). In the United States, appendectomy incurs considerable indirect costs resulting from time lost from work, school, or usual activities after the procedure.³⁵ The individual lifetime risk of appendicitis is 8.6% for men and 6.7% for women.³⁶ Uncomplicated acute appendicitis is considered almost universally to be an indication for an appendectomy. In 1894, open appendectomy was accepted as the treatment standard, because it saved lives, and since that time, the dictum that surgical removal of the appendix is necessary has been largely unchallenged.³⁷ All surgeons are taught that appendicitis untreated will march on and eventually perforate which puts the patient's recovery in question. Thus, early surgical exploration and appendectomy is advocated for source control. However, appendectomy for nonperforated appendicitis is not without associated harm. The long-term risk of small bowel obstruction is estimated at 1.3% at 30 years after appendectomy.³⁸ In addition, the "negative" appendectomy rate ranges from 10% to 20%, and remains unchanged despite the widespread use of CT.³⁹⁻⁴¹

Meanwhile, nonoperative management with antibiotics has been established as the treatment for various intra-abdominal infections such as uncomplicated diverticulitis, salpingitis, and neonatal enterocolitis.⁴² It is surprising that nonoperative management of uncomplicated acute appendicitis remains largely unexplored despite evidence that it often resolves, either spontaneously or with antibiotic therapy, and has been shown by limited studies to have outcomes equivalent to those of appendectomy.^{43,44} Accordingly, it may be reasonable to call into question the assumptions and "evidence" that have supported routine appendectomy for this condition.

Spontaneous resolution of appendiceal inflammation does occur, although its frequency is unknown. Presumably, increasing intraluminal pressure dislodges the obstructing material back into the cecum, thereby relieving the distention and inflammatory process. Evidence of previous inflammation may be recognized subsequently as a fibrotic, kinked, or adhered appendix when viewed at a future operation. In 1 series of 1,000 patients with appendicitis, 9% reported having had a similar clinical illness in the past and 4% reported more than one previous attack.⁴⁵

Widespread CT scan utilization for the diagnosis of appendicitis has resulted in a significant increase in the number of CT scans performed annually.⁴⁶ This has led to several interesting observations regarding the possibility of spontaneous resolution of appendicitis from several centers. Inclusion of a CT scan result in the Alvarado score has been shown to increase the rate of appendectomy. When classified as having a low likelihood of appendicitis (Alvarado score ≤ 4), patients who underwent a CT scan had an appendectomy rate of 48%.⁴⁶ In contrast, those with an Alvarado score ≤ 4 who did not undergo a CT scan had an appendectomy rate of only 12% suggesting that some percentage of the population resolved spontaneously.

Decadt and colleagues made a comparable observation for those patients who presented with nonspecific abdominal pain.⁴⁷ The investigators used diagnostic laparoscopy instead of CT scan in the management of patients with nonspecific abdominal pain. Patients were randomized to either (1) diagnostic laparoscopy or (2) nonoperative management (with operative intervention if peritonitis developed). The appendectomy rate was 39% for those randomized to diagnostic laparoscopy and 13% for those managed nonoperatively. These indirect findings and evidence are suggestive that uncomplicated, acute appendicitis may be initially managed nonoperatively.

Nonoperative Management of Acute Appendicitis

To date, there have been few randomized studies of nonoperative versus operative therapy for acute appendicitis, and none have been conducted in the United States. Several reports have appeared in the literature over the last half decade describing nonoperative management of acute, uncomplicated appendicitis.^{18,48-50}

The trial that has received the most attention was conducted in Sweden.⁴⁸ All patients older than 18 years with presumed appendicitis diagnosed by the physician based on clinical history, laboratory tests, US, CT, and physical examination were included. A total of 369 consecutive patients were randomized to antibiotic treatment or surgery. Study patients received intravenous (IV) antibiotics (cefotaxime 1 g twice and metronidazole 1.5 g once) for at least 24 hours. During this time patients received IV fluids with no oral intake. Patients whose clinical status had improved the following morning were discharged to continue with oral antibiotics (ciprofloxacin 500 mg twice per day and metronidazole 400 mg 3 times per day) for a total of 10 days. In patients whose clinical condition had not improved, IV treatment was prolonged.

There were 202 patients in the study group (antibiotics) and 167 patients in the control group

(appendectomy). In the study group, 106 (52.5%) completed the intended antibiotic treatment, and 154 (92.2%) in the control group underwent an appendectomy. Of 108 patients who initially improved without surgery, 15 (13.9%) had recurrent appendicitis at a median follow-up time of 1 year. One-third of recurrences appeared within 10 days following discharge from the hospital. Of the 15 patients with recurrence, 12 had surgery (4 patients had gangrenous or perforated appendicitis and 1 patient underwent ileocecal resection) and 3 had a second round of antibiotic treatment with success.

Efficacy in the study group according to intention to treat was 48.0% (97 of 202). Eleven of 119 (9.2%) patients who primarily received antibiotics had an appendectomy owing to clinical progression. The preoperative characteristics of these patients were similar to those of the patients who fulfilled the antibiotic treatment. Of 250 surgically explored patients, 223 (89.2%) had appendicitis. Primary treatment efficacy was 90.8% for antibiotic therapy compared to 89.2% for surgical exploration analyzed per protocol. Major complications and total hospital cost for the primary admission were both lower in the antibiotic treatment group. This study shows that nonoperative management is an option in properly selected patients.

One of the largest retrospective series reporting nonoperative management of appendicitis comes from Japan.⁵¹ Shindoh and colleagues reviewed their institutional experience with nonoperative management of appendicitis; in this report 367 patients met inclusion criteria (right lower-quadrant pain, WBC >9,000 or CRP >1.0 mg/dL). The authors describe the following three study groups: (1) initial operation or appendectomy, (2) nonoperative group, and (3) initial nonoperative group converted to surgery (failure). In the nonoperative groups, patients received antibiotics and were evaluated 24 hours later. If the physical examination or laboratory parameters worsened, surgical management was considered. In this cohort, 143 (39%) underwent initial operation (group 1), whereas 224 (61%) were managed with initial antibiotic therapy. In the initial nonoperative group, 91 patients did not respond to antibiotics and underwent appendectomy. Factors predictive of failure included CRP (odds ratio [OR] 5.5, 95% CI: 1.94 to 17.29) and the presence of an appendicolith (OR 4.7, 95% CI: 1.15 to 24.46). Of note, in this study recurrence of appendicitis was observed in 4.7% of patients initially managed nonoperatively.

One of the inherent difficulties and biases in conducting a well-planned randomized clinical trial, centers on pathologic confirmation of appendicitis. On one hand, for those patients with “suspected” appendicitis who receive antibiotics only, treatment successes may cause one to consider the underlying diagnosis (“is it really appendicitis?”). On the other hand, the number of patients who undergo a negative appendectomy is not zero and exposure of these patients to surgical risks and complications is a valid concern. The report by Hansson and colleagues demonstrated a threefold increased rate of complications in the appendectomy group when compared to the nonoperative, antibiotic only group.⁴⁸

4 The data presented are suggestive that in selected patients with acute, uncomplicated appendicitis, antibiotic treatment seems to be an appropriate alternative to appendectomy. Multivariate analysis of patient characteristics failed to demonstrate any logistic model for inclusion or rejection of patients for the specified treatments. A few of these studies have found that presence of the fecaliths is predictive of failure. Further studies are needed to create informed multivariate models that adjust for all of the important clinical covariates. Therefore, most patients older than 18 years without obvious signs of intra-abdominal perforation can be offered antibiotic treatment as first-line therapy. Clinical progression and surgical judgment may then determine whether there is a real need for surgical exploration. The benefit would be a significantly reduced frequency of major complications related to surgery, and potentially reduced costs.

Management of Complicated Appendicitis

Of the 11 of 10,000 people in the United States who will develop acute appendicitis over their lifetime,⁵ an estimated 2% to 6% of patients will present with an appendiceal mass, either in the form of an inflammatory phlegmon or abscess.⁵² The optimal management of these cases remains controversial. There is no consensus in the surgical literature on whether to proceed immediately with appendectomy or initial nonoperative management in this setting of complicated appendicitis. Another dilemma in the management of appendicitis initially managed conservatively with antibiotics is whether or not to perform an appendectomy at a later date (interval appendectomy). The data are disparate regarding actual recurrence rates of appendicitis following nonoperative management, but they are commonly reported between 5% and 20%.^{53–55} In addition to recurrent appendicitis, a clinical concern in older patients who present with a cecal phlegmon is malignancy. In these cases, interval appendectomy allows the correct pathologic diagnosis to be made.⁵⁶ The effect of these management decisions on duration of

hospital stay, number of interventions, healthcare costs, and overall patient satisfaction must be considered.

Figure 71-2. Perforated appendicitis.

Appendiceal Abscess

Appendiceal abscess is commonly associated with delayed presentation, fever, leukocytosis, and a palpable mass in the right lower quadrant (Fig. 71-2). The diagnosis is confirmed with CT or US. Management of these patients remains controversial. The traditional nonsurgical approach consists of percutaneous drainage and IV antibiotics, with or without interval appendectomy. Others suggest immediate appendectomy and surgical drainage of the abscess. The evidence supporting both approaches is weak, as most studies are retrospective and often combine patients with appendiceal abscess and phlegmon into a single cohort called “appendiceal mass.” Several meta-analyses have been performed to try to identify differences between the two treatment strategies. Andersson and Petzold performed a meta-analysis on 19 retrospective studies from 1969 to 2005. The limitation of this study is the lack of uniform definition of appendiceal abscess and phlegmon. Nevertheless, the meta-analysis revealed that nonsurgical treatment failed in 7.6% of patients (CI: 3.2 to 12.0). Immediate appendectomy is associated with a higher morbidity with an OR of 3.3 (CI: 1.9 to 5.6). Based on these findings, the authors recommended nonsurgical management of patients with appendiceal abscess.⁵³ Similar conclusions were reached by Simillis and colleagues, who performed a meta-analysis of 16 retrospective studies and 1 nonrandomized prospective study from 1969 to 2007, comparing immediate appendectomy (725 patients) versus nonsurgical treatment (847 patients).⁵⁷ Immediate appendectomy is associated with greater incidence of ileus or bowel obstruction, abdominal or pelvic abscess, and wound infection compared to nonsurgical treatment. There was no difference in the overall duration of hospitalization, but the immediate appendectomy group required more reoperations. The higher rate of complications associated with immediate appendectomy has been attributed to greater inflammatory response to surgery in the setting of infection, as well as the technical difficulty with inflamed tissue. Most of the studies analyzed in these meta-analyses utilized open appendectomy techniques. The potential disadvantages of early operation may be mitigated by the laparoscopic techniques. Laparoscopic appendectomy results in less local inflammation due to better visualization and instrumentation.⁵⁸

St. Peter and colleagues conducted a prospective randomized trial comparing immediate laparoscopic appendectomy to nonsurgical treatment in 40 pediatric patients presenting with appendiceal abscess.⁵⁹ Immediate laparoscopic appendectomy tends toward longer operative time (61 minutes vs. 42 minutes) compared with interval laparoscopic appendectomy performed at 10 weeks from initial presentation. The immediate appendectomy group had fewer healthcare visits and few CT scans. However, there was no difference in recurrent abscess rate, total length of hospitalization, or total charges. They concluded that immediate laparoscopic appendectomy is as safe as nonsurgical management. The safety of immediate laparoscopic appendectomy for appendiceal abscess is supported by several other retrospective or uncontrolled studies.^{60–63} The infectious complications of immediate appendectomy can be reduced by improved laparoscopic techniques, such as use of extraction bag, endostaplers rather than endoloops, and limited irrigation to avoid bacterial contamination.^{64,65}

Appendiceal Phlegmon

The management of acute appendicitis complicated by an appendiceal phlegmon typically involves 1 of 3 treatment strategies (Fig. 71-3). The first, and most commonly accepted, is initial treatment with broad spectrum antibiotics and IV fluids until the acute inflammation subsides; appendectomy is then performed on an interval basis. Another strategy involves appendectomy upon initial presentation. Finally, following resolution of the acute inflammation with broad spectrum antibiotics, the patient is managed expectantly without interval appendectomy. Prospective data comparing these strategies are sparse, with most systematic reviews drawing heavily upon retrospective data.

Figure 71-3. Perforated appendicitis with associated abscess.

Interval Appendectomy

The presence of an appendicolith associated with an appendiceal phlegmon deserves special mention, as its presence has been used as a guide to proceed with interval appendectomy following successful nonoperative management. A retrospective cohort study reviewed the outcomes of 96 pediatric patients

with appendicitis who presented with either an inflammatory mass or phlegmon, and were initially managed nonoperatively by the staff surgeon.⁶⁸ Six patients who failed initial nonoperative management underwent appendectomy and were excluded. Forty-one patients were scheduled for elective appendectomy by their surgeon and were also excluded from analysis. The remaining patients were included in the study and their outcomes over a 2-year period were reported. Of these, 37% had an appendicolith and 63% did not. The overall recurrence rate for appendicitis was 42%; in patients with an appendicolith, the recurrence rate was 72% compared to 26% in patients without an appendicolith (relative risk of 2.8 in patients with an appendicolith). The authors concluded that the presence of an appendicolith predicts failure of nonoperative management of periappendiceal phlegmon or abscess. It is important to note that the overall recurrence rate of appendicitis in this study is higher than what is typically reported elsewhere in the literature, and this may influence the true effect of an appendicolith on failure of nonoperative management.

Unfortunately, there are no data from a randomized, prospective trial evaluating whether or not the presence of an appendicolith is predictive of failure of initial nonoperative management of ruptured appendicitis with phlegmon or abscess. As such, any conclusions from this study should be viewed as hypothesis-generating for a future randomized controlled trial.

In deciding whether or not to proceed with routine interval appendectomy following successful nonoperative management of an appendiceal phlegmon or abscess, the effect of cost must also be considered.⁶⁹ Even with a high probability of recurrent appendicitis (assumed to be 40%), financial analysis does not favor elective interval appendectomy.

A more robust randomized trial looking at the return to normal activity examined 131 total patients enrolled: 64 receiving initial appendectomy, and 67 were assigned to interval appendectomy.⁷⁰ In the primary appendectomy group, time to normal activity was 13.8 versus 19.4 days in the interval appendectomy group ($P < 0.001$). Of note, the relative risk of any adverse event associated with interval appendectomy was 1.86; specific outcomes measured included intra-abdominal abscess, small-bowel obstruction, unplanned readmission, and recurrent appendicitis, and these were all seen with higher frequency in the interval appendectomy group. The authors conclude that early appendectomy significantly reduced the time away from normal activity and showed a significantly lower adverse event rate.

5 The optimal management strategy of an appendiceal phlegmon or abscess remains elusive as most recommendations are based on retrospective data, but recent randomized trials in children indicate that early appendectomy results in faster return to normal activity with favorable complication rates when compared to interval appendectomy.⁷⁰ Performing an interval appendectomy following successful nonoperative management with antibiotics and percutaneous drainage, as needed, has yet to be evaluated in a randomized trial. Higher-quality evidence from prospective, randomized trials will help surgeons decide whether or not interval appendectomy in the setting of an appendicolith is appropriate.

SURGICAL OPTIONS FOR ACUTE APPENDICITIS

Laparoscopic versus Open Appendectomy

The open appendectomy was initially described by McBurney in 1894, and has remained relatively unchanged since its introduction. In 1983, Semm described a laparoscopic approach for removing the appendix, advocating the advantages of laparoscopic surgery for one of the most frequently performed surgical procedures.⁷¹ Since open appendectomy also typically involves a small incision, short hospital stay, rapid return to normal activity, and low postoperative morbidity, demonstrating clear superiority of one approach over the other has been elusive. Although many randomized control trials comparing open versus laparoscopic appendectomy have been performed, many contain methodologic flaws, including inadequate allocation concealment, lack of reporting of randomization method, failure of adequate blinding, lack of analysis by intention-to-treat, and incomplete follow-up data.⁷² That being said, these randomized trials, as well as systematic reviews and meta-analyses of these studies, have provided a great deal of insight into the specific benefits and drawbacks of each approach. In deciding between a laparoscopic and open approach, specific issues that must be considered include learning curve, operative time, associated morbidity, cost, pain, cosmesis, hospital length of stay, and time to return to normal activity. Unfortunately, measures vary across studies and conclusions have been inconsistent.

A large retrospective review of prospectively acquired data, compared outcomes of laparoscopic

versus open appendectomy in 222 hospitals participating in the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) was conducted by Ingraham and colleagues.⁷³ The analysis of 30-day outcomes following laparoscopic and open appendectomy showed overall morbidity, serious morbidity, surgical site infection, and serious morbidity or mortality to be higher in patients undergoing open appendectomy, although these complications were generally low in both groups. A Cochrane review of 67 trials comparing laparoscopic and open appendectomy was updated in 2010.⁷⁴ Of these studies, the vast majority (56) were conducted in adults. Outcomes assessed by the included trials most frequently included operating time, complication rates, hospital stay, pain, and return to normal activity.

6 Although a variety of complications were evaluated, due to inconsistencies in the definition and reporting of these complications, the authors only examined two specific complications in their analysis: wound infection and intra-abdominal abscess. Following laparoscopic appendectomy, wound infections were approximately one-half as likely when compared to open appendectomy (OR 0.43; 95% CI: 0.34 to 0.54). Conversely, laparoscopic appendectomy was associated with a nearly threefold increase in the likelihood of intra-abdominal abscess when compared to an open technique (OR 1.77; 95% CI: 1.14 to 2.76). Operative time was 10 minutes longer for laparoscopic appendectomy (95% CI: 6 to 15), but this difference has been decreasing in recently published trials. Laparoscopic appendectomy was also associated with lower postoperative pain, shorter hospital stay (1.1 days), and faster return to normal activity (5 days), although these results are highly heterogeneous and further study is warranted. Hospital and operational costs are higher with laparoscopic appendectomy, but again, these results are strongly heterogeneous. The authors concluded that laparoscopic appendectomy confers many benefits over open appendectomy, and should be strongly considered as the preferred approach where surgical expertise is appropriate and equipment is available and affordable.

The question of whether or not appendectomy should be performed via an open or laparoscopic technique has been inherently difficult to answer because both approaches offer similar advantages, namely, a small incision, low incidence of complications, a short hospital stay, and rapid return to normal activity. Newer studies would favor laparoscopic approaches but the answer is still not definitive. Ultimately the surgical approach remains up to the surgeon. Well-trained surgeons should be facile in both approaches should the need arise.

Single-Incision (Single-Port) Laparoscopic (SILS) Appendectomy

In the evolving era of “scarless surgery,” SILS has been utilized for appendectomy. A single-incision laparoscopic-assisted appendectomy for acute appendicitis was first reported in adult patients in 1992.⁷⁵ Soon thereafter, this surgical approach began to be reported in children, with the first reports utilizing a single umbilical incision with a laparoscopic-assisted appendectomy, in which the appendectomy was performed after exteriorization through the umbilical incision.⁷⁶ Since then, several techniques under the auspices of SILS have been utilized including natural orifice transluminal endoscopic surgery and many variations of single-incision techniques.^{77–80} The touted advantages of the SILS approach to appendectomy are similar to general laparoscopy compared to open operations, including less pain, faster recovery, and better cosmesis. However, critics countered these with concerns about increased costs, longer operation times, and higher complication rates.⁸¹

In adult studies comparing SILS with conventional three-port laparoscopic appendectomy, advantages in cosmetic outcomes were at the cost of longer operation times and substantial early postoperative pain.⁸² SILS is even more popular in children without significant data that show a benefit. Oltmann and colleagues⁸³ reported that SILS with appendectomy is feasible and safe in the pediatric population. Although operating times were longer than the conventional three-port laparoscopic appendectomy, the authors suggested these should improve with better instrumentation and experience. St. Peter and colleagues⁸⁴ reported on the only randomized control trial comparing SILS-assisted appendectomy to conventional three-port laparoscopic appendectomy in 160 children with nonperforated acute appendicitis. Utilizing an extracorporeal appendectomy, there was a nonsignificant difference in wound infection rates of 3.3% for SILS patients compared to 1.7% for conventional laparoscopy. Although there was a statistically significant difference in operative time between the two approaches, the SILS technique was only 5.4 minutes longer (29.8 ± 11.6 vs. 35.2 ± 14.5 minutes). The investigators suggested that the difference was not clinically relevant and both techniques had comparable outcomes.

Operative Approach in Complicated Appendicitis

Clinical evidence that supports the laparoscopic approach for complicated (perforated or intra-

abdominal abscess) appendicitis remains controversial. The concern over greater incidence of intra-abdominal abscess following the laparoscopic approach was reported in some studies^{85–87} but not supported by others.^{88,89} Due to the increased morbidity associated with complicated disease, some surgeons have opted for an initial nonoperative approach.^{70,84,90} Using nonoperative treatment for complicated appendicitis followed by interval appendectomy obviates the need to manage the inflammatory environment in the acute stage. Such a strategy has been shown to be successful in treating most of the cases of complicated appendicitis with shorter hospitalization, lower charges, and lower morbidity.^{91,92}

Outpatient Appendectomy

Traditionally, patients are hospitalized for 24 hours after laparoscopic appendectomy. As we move toward laparoscopic appendectomy becoming a new standard, the question has arisen if this surgery can be done as an outpatient operation. Although this strategy has been advanced in many elective abdominal procedures – laparoscopic cholecystectomy,⁹³ gastric bypass,⁹⁴ and incisional hernia repair,⁹⁵ for example – surgeons remain hesitant to discharge patients on the day of emergency surgery, particularly one with an infectious etiology. As recently as 2004, the average length of stay for laparoscopic appendectomy was 2.06 days.⁹⁶

Most protocols in the literature describe discharge after a set of criteria has been reached. Utilizing these protocols it has been shown that discharge can occur as soon as 171 minutes after completion of the surgery.⁹⁷ This is true regardless of the time of day the surgery was completed. In the largest published adult series, 55% of the patients were discharged between the hours of 6 PM and 6 AM.⁹⁷ Other studies confirm that a protocol for outpatient appendectomy can be successful for early same day discharge.^{98,99} In a study of 179 children 158 were targeted for same day discharge. Twenty-one patients were excluded due to findings of perforated or gangrenous appendicitis. One hundred and twenty six (80%) were discharged the same day as surgery with exceptions being made for social issues (too late at night or families unwilling to leave).¹⁰⁰

The studies to date, have been unable to show a difference in morbidity in the groups when comparing immediate discharge to patients who are admitted.^{96,97,99,101} In the largest of the studies on the topic postoperative complications occurred in 2.4% of outpatients and 11.7% per cent of inpatients ($P = 0.16$). Complications included superficial wound infections, urinary retention, urinary tract infection, intra-abdominal bleeding, pneumonia, and infected hematoma. Based upon the data, the authors concluded that outpatient laparoscopic appendectomy can be performed safely in selected patients.⁹⁸

7 Certainly from an economic standpoint, an argument could be made for this transition to outpatient surgery for uncomplicated appendicitis. Length of stay following laparoscopic appendectomy for uncomplicated appendicitis ranges from 1.6 days to 2.1 days.¹⁰² If an outpatient protocol were applied universally, it could result in annual healthcare savings of \$920 million. Even a more conservative estimate done in Canada comparing outpatient appendectomies to same day discharges showed a cost saving of \$323 Canadian dollars per patient.⁹⁹

APPENDICEAL NEOPLASMS

8, 9 Approximately 1% of all appendectomy specimens will contain a neoplasm.¹⁰³ The most common tumors are carcinoid, benign mucocoeles, and mucinous carcinoma. Rare tumors of the appendix include adenoma, adenocarcinoid, lymphoma, and GI stromal tumors. Appendiceal cancer is a rare disease, yet its incidence in the reported literature varies depending on the histologic types included in the classification of appendiceal malignancies. Historic evidence suggests that appendiceal primaries are diagnosed in approximately 1% of all appendectomy specimens.^{103–105} In a SEER database retrospective analysis that excluded low-grade carcinoid tumors, the annual age-adjusted incidence of appendiceal primaries was 0.12 cases per 1,000,000 of population. Appendiceal adenocarcinoma represented 66.5% of these patients.¹⁰⁶ Extrapolating from the SEER data, the annual incidence of the appendiceal adenocarcinoma in the country should be around 300 to 400 cases, although estimates up to 2,000 cases annually in the United States have been made. This incidence approximates the estimate that the appendix represents approximately 1% of the mucosal surface of the colon, with 137,000 cases of colorectal carcinoma in the United States encountered annually.¹⁰⁷ The rate of appendiceal neoplasms seems to be increasing.

There are no reliable early symptoms of appendiceal cancer, which, in part, explains why the majority of these patients are diagnosed incidentally during surgical exploration or late when peritoneal or systemic dissemination has already occurred. The rarity of appendiceal neoplasms makes screening programs unrealistic, and they are found by colonoscopy in <10% of cases.¹⁰⁸

The treatment of appendiceal neoplasms depends upon type, stage, and medical comorbidities; not all appendiceal tumors demand the same therapy, operative or otherwise. Interestingly, appendiceal adenocarcinomas are associated with secondary tumors in up to 35% of patients, most often involving other areas of the GI tract.¹⁰⁹

Mucocele

Mucocele of the appendix refer to a distended mucin-filled organ, which can be due to either benign (cystadenoma) or malignant (cystadenocarcinoma) disease (Fig. 71-4). Such mucoceles are due to an obstructed appendiceal lumen, leading to a large mucin-filled structure, often with calcification in the wall. Such lesions can be readily diagnosed by CT scans, and are often incidental findings. A simple appendectomy is curative for benign cystadenomas. Resection should be done with great care so as not to rupture the lesion, which can lead to dissemination. With rupture, whether of a histologically benign or even more commonly with a malignant cystadenocarcinoma, peritoneal tumor implantation can occur, leading to mucinous ascites, and a condition known as pseudomyxoma peritonei (PMP, see below). The presence of epithelial cells in the mucin extruded from the mucocele at the time of rupture greatly increases the likelihood of recurrence. Due to the potential for malignancy, and possible sequelae of rupture (spontaneous or iatrogenic), appendectomy should be performed in otherwise healthy patients.

Appendiceal Adenocarcinoma

Appendiceal adenocarcinoma typically presents either with symptoms suggestive of appendicitis or symptoms related to peritoneal dissemination. CT or MRI imaging is preferred and PET imaging is of little value in these cases.^{110–113} Appendiceal adenocarcinoma represents an unusual neoplasm, which has several variants. Mucinous appendiceal carcinoma is the most common, with colonic type or the signet-ring variant being less common, and associated with poorer outcomes.¹¹⁴ Appendiceal carcinomas are now more common than carcinoid (neuroendocrine) tumors. The appendiceal carcinomas are further subdivided into low- and high-grade lesions.^{115,116} Low-grade lesions (sometimes also known as disseminated peritoneal mucinous tumors) have more than double the long-term survival rate of high-grade lesions. Signet-ring cells are associated with a poorer prognosis. For known high-grade appendiceal carcinoma without peritoneal or distant metastasis, a right colectomy is appropriate surgical therapy. Those found to have nodal metastases should be considered for systemic chemotherapy, with regimens used for colon carcinoma.

Figure 71-4. A: Mucocele. B: Mucocele (opened).

In patients with appendiceal carcinoma, peritoneal dissemination is frequently found at presentation (50% of high-grade and 20% of low-grade lesions),¹¹⁴ and begins with tumor-induced obstruction of the appendiceal lumen. The obstruction in the face of continued mucin production eventually leads to perforation, and subsequent dissemination of mucous-producing epithelial cells throughout the peritoneal cavity. The pattern of spread is clearly related to the grade of disease. Low-grade mucin-

producing lesions are associated with implantation, and spread along the peritoneal surfaces with distant or lymphatic metastases in less than 10% of cases. A typical pattern of peritoneal dissemination begins in the right lower quadrant of the abdomen followed by the pelvis, right upper quadrant, then diffusely throughout the peritoneal spaces. This is distinguished from high-grade lesions, which have more substantial risks of nodal and systemic metastasis, resulting in poorer prognosis. In addition, approximately 7% of the low-grade lesions have lymph-node involvement, and another 16% will dedifferentiate into higher-grade lesions during the course of the disease.^{117,118}

The rarity of the disease has unique implications in diagnosis, classification, terminology, and treatment. Therefore, several misconceptions are still prevalent among clinicians. First, due to the fact that the majority of PMP cases occur in association with appendiceal primaries the term “pseudomyxoma peritonei” has been used as synonym with the variant of appendiceal-induced peritoneal surface disease associated with excessive production of mucin. Although most PMP is indeed from appendiceal neoplasms, the term is descriptive and can be applied to any primary (including ovarian, colon, or even pancreatic mucinous) cancer that has the ability to produce mucinous ascites.¹¹⁹ Consequently, the term PMP would be better used as a clinical sign rather as a distinct disease. Second, not all mucinous appendiceal tumors are associated with long-term survival. Factors such as histologic grade, tumor biology of the primary lesion,¹²⁰ age, functional status of the patient, and extent of disease at the time of diagnosis determine the prognosis of these patients. Third, not every appendiceal primary is associated with mucin production or ascites. Many patients present with peritoneal disease that has no phenotypic difference from any other gastrointestinal malignancy with peritoneal dissemination (Fig. 71-5).

10 The management of patients with peritoneal surface disease from appendiceal neoplasms is still a matter of debate. These patients have been traditionally treated with debulking procedures or systemic chemotherapy alone.^{119,121,122} Right colectomy does not seem to convey a survival advantage in patients with peritoneal dissemination.¹²³ Though low-grade appendiceal tumors treated with limited debulking procedures can provide some patients with prolonged survival, more than 90% of these patients will inevitably develop local recurrence and death from bowel obstruction.¹²¹ To deal with the problem of postdebulking residual microscopic disease, a variety of “adjuvant” therapies have been evaluated. Intraperitoneal photodynamic therapy, radiation (with 32P), and chemotherapy instillation have been tried and largely abandoned. In 1980, hyperthermic intraperitoneal perfusion was described by Spratt.¹²³ Sugarbaker subsequently published his early experience in combining cytoreduction with heated intraperitoneal chemotherapy.^{124,125} This combined approach of aggressive cytoreduction combined with HIPEC has since been more thoroughly evaluated at many centers.¹²⁶ HIPEC is now considered a standard of care in the treatment of peritoneal dissemination from appendiceal cancer (Fig. 71-6).

Figure 71-5. Mucinous appendiceal neoplasm with pseudomyxoma peritonei.

Figure 71-6. Completed perfusion circuit (closed abdomen technique), with dual inflow and outflow cannulas.

Most experienced centers approach to peritoneal dissemination from appendiceal tumors has been aggressive cytoreduction surgery, with the goal of removal of all gross disease if feasible. Selection criteria should include a resectable primary lesion, resectable peritoneal disease, freedom from extra-abdominal disease, and good performance status. The resection typically entails peritonectomy procedures, omentectomy and potentially multivisceral resection (if the peritoneal disease cannot be stripped from the organ). The cytoreductive phase is followed by hyperthermic intraperitoneal chemotherapy (HIPEC), see figure. Mitomycin is the standard agent used in the perfusate, with perfusions running for 30 to 120 minutes depending upon the center. This is typically administered with mild hyperthermia (40 to 43°C), as elevated temperatures are associated with enhanced antineoplastic effect in vivo, and help maintain normothermia after cytoreduction. After completion of the HIPEC, the patient is definitively closed. If complete cytoreduction is achieved, at an initial procedure, if the disease recurs, selected patients may undergo repeat exploration and perfusion as dictated by their performance status and symptoms.¹²⁷ Patient selection and the demands of cytoreduction have significant learning curves and are best not performed by the occasional operator.^{128,129} Patients with low-grade disease who undergo complete cytoreduction and HIPEC have 10-year survival rates in the 70% to 80% range.¹²⁹⁻¹³¹ These cytoreductive procedures can be formidable procedures, and have been associated with considerable morbidity, however more recent experience from major centers suggests improvements and complication rates which are in keeping with those expected for major procedures on patients with disseminated malignancy.^{128,129,132,133}

Systemic chemotherapy for peritoneal surface disease from low-grade appendiceal neoplasms is largely ineffective. This is due to both the inability of systemically delivered drugs to reach effective intraperitoneal concentrations, and the slow-growth kinetics of the malignant cells. A phase II study in advanced unresectable low-grade appendiceal primaries, with concurrent mitomycin C and capecitabine, showed a “response” in 38% of the patients in the form of either stabilization or radiologic reduction in the volume of disease.¹³⁴ For high-grade lesions it seems that systemic chemotherapy improves progression-free survival, even after a HIPEC with complete cytoreduction.^{135,136} Chemotherapy with FOLFOX, in the preoperative setting for high-grade appendiceal mucinous lesions, was found to have progression of disease in 50% of the patients, and significant tumor response observed in 29% of cases.¹³⁷ In addition, several groups have evaluated a number of alternative treatment modalities including photodynamic therapy,¹³⁸ and external beam radiation therapy.¹¹⁹ None of these treatments have significantly altered the clinical course of these patients.

Carcinoids

Approximately one-third of all appendiceal neoplasms are carcinoids, which are tumors of neuroendocrine/neural crest origin. Of all carcinoid tumors within the GI tract, approximately half arise within the appendix. Carcinoid tumors of the appendix are usually found incidentally on pathologic examination of the inflamed appendix. Most appendiceal carcinoids are <2 cm in size and arise in or near the tip, thus they rarely cause obstruction. These tumors have a characteristic firm yellow appearance, and when advanced, may be associated with a surrounding desmoplastic reaction. Approximately 25% of cases present with nodal metastases and 10% with distant metastases.¹³⁹⁻¹⁴¹ Tumor markers (such as CEA, chromogranin, or urinary hydroxyindole acetic acid) may be useful for following up carcinoid cases, and should be obtained prior to resection.

In regard to treatment and prognosis, the key feature is the size of the tumor. Most carcinoids are small and those <1 cm in diameter, are adequately treated by simple appendectomy. Lesions between 1 and 2 cm have a 7.5% risk of nodal disease and a 4% risk of distant metastasis, while those larger than 2 cm have a 33% risk of nodal disease, and a 12% risk of distant metastasis.¹⁴² For lesions 2 cm in size or greater, a right hemicolectomy is indicated, principally for the attendant lymphadenectomy.¹⁴² For lesions between 1 and 2 cm, right colectomy is considered for high-grade malignant lesions with a high mitotic index, mesoappendiceal invasion, lymphovascular invasion, tumors located at the base of the appendix with positive margins, and goblet cell adenocarcinoid tumors.¹⁴³ Overall survival at 5 years approaches 100% for node-negative lesions <3 cm, 85% for node-positive lesions and 30% for metastatic lesions.¹⁴⁴ Appendiceal carcinoids are associated with liver metastases, and in these cases the carcinoid syndrome may be present. The number and location of liver lesions, as well as the associated symptoms, dictates treatment in these cases.^{142,144}

Carcinoid syndrome is typically treated with somatostatin analogs as well as systemic chemotherapy. There is a role for debulking of metastases, which may result in improved quality of life and overall survival for those with the paraneoplastic carcinoid syndrome.

SECTION J: HERNIA AND SPLEEN

Chapter 72

Abdominal Wall Hernias

Robert J. Fitzgibbons, Jr., Thomas H. Quinn, and Devi Mukkai Krishnamurty

Key Points

- 1 Surgeons have traditionally been taught the anatomy of the abdominal wall from an outside to inside perspective. However, with the increasing use of intra-abdominal or preperitoneal approaches to abdominal wall reconstruction, a better understanding of the anatomy from the inside to the outside perspective is important.
 - 2 Major risk factors for the development of an abdominal wall hernias include chronic obstructive pulmonary disease, smoking, high intra-abdominal pressure, collagen vascular disease, thoracic or abdominal aortic aneurysm, peritoneal dialysis, matrix metalloproteinase (MMP) abnormalities, and an increased type I: type III collagen ratio.
 - 3 Inguinal hernias constitute approximately 75% of abdominal wall hernias, with femoral hernia accounting for 5%. Femoral hernias are more common in women, but a woman with a groin hernia is still five times more likely to have an inguinal hernia (usually indirect) than a femoral. Incisional, umbilical, and epigastric hernias account for 15%, and miscellaneous hernias make up the other 5%.
 - 4 The literature dealing with groin hernia in women is insufficient making management decisions difficult.
 - 5 Watchful waiting is an acceptable alternative to routine repair for male inguinal hernia patients with minimal symptoms. This does not apply to females because of the higher risk of a hernia accident. Patients in the watchful waiting group should be aware of the likelihood long-term crossover into treatment group.
 - 6 The performance of a “tension-free” inguinal hernia repair dramatically reduces the risk of recurrent hernia to a rate generally reported to be less than 2%.
 - 7 The frequency of at least some long-term groin pain after inguinal herniorrhaphy is approximately 10% at 1 year with moderate to severe pain in 1% to 2%.
 - 8 Abdominal wall dynamics are better addressed with muscles re-approximated, contributing to improved quality of life and patient satisfaction.
 - 9 Abdominal wall reconstruction and component separation are useful tools in the armamentarium of the hernia surgeon.
 - 10 Historical recurrence rates of 30% to 40% following ventral hernia repair have been dramatically reduced by modern tension-free repairs.
-

One of the most frequently performed operations by general surgeons worldwide is the repair of an abdominal wall hernia. According to the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), in the years 2009–2010, abdominal wall hernias were responsible for 3.6 million ambulatory care visits, 380,000 hospitalizations, and 1,322 deaths in the United States.¹ In the past, most training programs relegated the repair of abdominal hernias to the junior members of the surgical team with little regard for results.² However, in the modern era of heightened emphasis on accountability to our patients, this is changing rapidly. Interest by the academic community in the science behind hernia repair as well as an explosion in device development by industry has resulted in significant changes in many surgeons’ practices. In this chapter, we have provided a detailed description of the abdominal wall anatomy, an understanding of which is key in the success of a hernia repair. We have then described the different treatment options with their available evidence and have included some of the newer developments in the field of hernia surgery.

ANATOMY OF THE ABDOMINAL WALL AND GROIN

1 Surgeons have traditionally been taught the anatomy of the abdominal wall from an outside to inside perspective. However, with the increasing use of intra-abdominal or preperitoneal approaches to abdominal wall reconstruction, a better understanding of the anatomy from the inside to the outside perspective is important. The anatomy of the abdominal wall and the inguinal region are presented, first from the viewpoint of the surgeon using open techniques and subsequently from the perspective of the surgeon utilizing the laparoscope. Anatomic terms for which synonyms and eponyms are commonly used are listed in [Table 72-1](#). Specific anatomic nomenclature can now be found in *Terminologia Anatomica*, the successor to *Nomina Anatomica*.

The abdominal wall spans the gap between the lower ribs and the pelvis; the lowest ribs, pelvic brim, and lumbar spine comprise its only skeletal support. The muscular and aponeurotic structures that provide much of the integrity of the wall must not only compress and contain abdominal viscera but also contribute to the support and movement of the spine and pelvis.

The sheets of relatively thin muscles and aponeuroses that make up the abdominal wall would, individually, seem to predispose to visceral eventration. However, the laminar layout of these sheets over most of the wall precludes this in most cases. The most common sites of hernia formation are found between laminations, where only peritoneum and fascia are found between the viscera and skin. These weak areas are most important to the hernia surgeon and are described in detail in the subsequent sections dealing with the anterior and posterolateral abdominal wall and the inguinal region.

Anterior Abdominal Wall

Superficial Fascia, Vessels, and Nerves

The anterior abdominal wall does not consist solely of muscle and aponeurosis; it can also be the repository for copious amounts of adipose tissue (panniculus adiposus) in its superficial fascial layer, often called *Camper fascia*. This layer, which is continuous inferiorly with the outer layer of fascia covering the perineum and genitalia, also contains the dartos muscle fibers of the scrotum. The major blood vessels of the superficial fatty layer are the superficial epigastric vessels and superficial circumflex iliac vessels, which are tributaries of the femoral vessels. The superficial fascia is also replete with lymphatic vessels that drain into the inguinal lymph nodes inferior to the umbilicus. The lymphatic structures cross the inguinal ligament, so that they are potentially placed in the surgical field during open herniorrhaphy.

Table 72-1 Anatomic Terms with Common Synonyms and Eponyms

Fascial Structures/Spaces
Fatty layer of superficial fascia; panniculus adiposus; Camper fascia
Investing fascia of external abdominal oblique; fascia innominata
Membranous layer of superficial fascia; Scarpa fascia
Retroinguinal space; space of Bogros
Retropubic space; space of Retzius
Ligamentous Structures
Iliopectineal ligament; iliopectineal arch
Iliopubic tract; Thompson ligament (band)
Inguinal ligament; Poupart ligament
Lacunar ligament; Gimbernat ligament
Pectineal ligament; Cooper ligament
Aponeurosis-Derived Structures
Arcuate line; semicircular line; linea semicircularis; line of Douglas
Falx inguinalis (often incorrectly referred to as <i>conjoined tendon</i>)
Reflected inguinal ligament; reflex ligament; Colles ligament
Semilunar line; linea semilunaris

A second fascial layer in the superficial abdominal wall is the deep fascia of Scarpa. Although most commonly considered a distinct anatomic layer, Scarpa fascia actually consists of compressed fibrous components of the superficial fascia.³ The deeper fibrous tissue of the superficial fascia forms the

fundiform ligament of the penis (suspensory ligament of the female clitoris), continues onto the penis and scrotum, and ultimately fuses with the superficial fascia of the perineum.

Figure 72-1. The myopectineal orifice. Superior to the inguinal ligament, this area includes the inguinal (Hesselbach) triangle. Inferior to the ligament, the orifice transmits the iliopsoas muscle, the femoral nerve and vessels, and the femoral canal and sheath. (Reproduced with permission from Wantz GE. *Atlas of Hernia Surgery*. New York, NY: Raven Press; 1991:4.)

The superficial fascia also fuses with the layer of fascia (fascia innominata) investing the external abdominal oblique muscle. This fascia is bound inferiorly to the inguinal ligament and pubis before continuing onto the thigh, where it blends with the fascia lata to seal the space beneath and inferior to the inguinal ligament, which is the inferior portion of the myopectineal orifice (Fig. 72-1). This portion of the inguinal region includes the Hesselbach (inguinal) triangle superiorly and therefore constitutes the weakest aspect of the groin.

The skin of the anterior abdominal wall is segmentally innervated in the familiar dermatome pattern. The nerve branches to this area are derived from the anterior and lateral cutaneous branches of the ventral rami of the 7th to 12th intercostal nerves and from the ventral rami of the first and second lumbar nerves. Disruption of one of these nerves is rarely noted by the postoperative patient because the dermatome fields overlap significantly. The anterior and lateral cutaneous branches reach the subcutaneous layer by coursing between the flat lateral muscles and by piercing the sheath of the rectus abdominis.

Anterior Musculature and Ligaments

The division of the wall into anterior and posterior segments is somewhat artificial because the anterior muscles, with the exception of the rectus abdominis, arise posteriorly and also form part of the posterior wall.

The three muscles of the lateral aspect of the anterior abdominal wall (Fig. 72-2) are composed of a variable amount of muscle with a large aponeurosis. The aponeurosis is the tendon of insertion for the lateral muscles, and it also forms the sheath of the rectus abdominis. The midline decussation of the three aponeuroses forms the linea alba. Fibrous tissue layers are of great importance to the hernia surgeon because of their ability to support sutures. *Fascia* and *aponeurosis* are terms commonly used to describe these fibrous structures, but are often confused and used interchangeably. In this chapter, an aponeurosis is defined as the non-muscle-fiber-containing portion of a muscle usually present at insertion points. Muscle fibers are said to “give way” to the corresponding aponeurosis. Fascia, on the other hand, is the fibrous tissue that lines or envelops muscles.

Figure 72-2. Pattern of crossing of the aponeurotic fascicles of the abdominal wall musculature. **A:** Fascicles from the right external oblique and anterior lamina of the left internal oblique. **B:** Fascicles from the right transversus abdominis and posterior lamina of the left internal oblique. **C:** Fascicles between the right and left transversus abdominis muscles.

External Abdominal Oblique Muscle and Associated Ligaments

The external abdominal oblique muscle (Figs. 72-2 and 72-3A,B) is the most superficial of the three lateral abdominal muscles. The external abdominal oblique arises from the posterior aspects of the lower eight ribs and interdigitates with both the serratus anterior and the latissimus dorsi at its origin. The direction of the muscle fibers varies from nearly horizontal in its upper portion to oblique in the middle and lower portions. The mostly horizontal fibers, which originate posteriorly, insert onto the anterior portion of the iliac crest. The obliquely arranged anteroinferior fibers of insertion fold on themselves to form the inguinal ligament. The remaining portion of the aponeurosis inserts into the linea alba after contributing to the anterior portion of the rectus abdominis sheath. Some fibers cross the linea alba to reinforce further the anterior rectus sheath of the opposite side.

The more medial fibers of the aponeurosis of the external oblique divide into a medial and a lateral crus to form the external or superficial inguinal ring. The spermatic cord (or round ligament) and branches of the ilioinguinal and genitofemoral nerves pass through this opening. The *inguinal ligament* (Fig. 72-4) is worthy of special consideration because of its important role as both a landmark and an integral component of many groin hernia repairs. The inguinal ligament is formed by obliquely oriented anteroinferior aponeurotic fibers of the external abdominal oblique. The ligament is formed when the aponeurosis folds beneath itself. Its lateral attachment is to the anterior superior iliac crest; its medial insertion is primarily on the pubic tubercle.

The medial insertion of the inguinal ligament in most persons is dual. One portion runs along the superior surface of the pubic tubercle and symphysis to form (or at least reinforce) the superior pubic ligament. The other portion is fan shaped and spans the distance between the inguinal ligament proper and the pectineal line of the pubis. This fan-shaped portion of the ligament is called the *lacunar ligament* (Fig. 72-4). It blends laterally with the pectineal (Cooper) ligament.

Internal Abdominal Oblique Muscle and Aponeurosis

The middle layer of the lateral abdominal group is the internal abdominal oblique muscle (Figs. 72-2 and 72-3B,C). This muscle primarily arises from the iliac fascia along the iliac crest and forms a band of iliac fascia fused with the inguinal ligament. The uppermost fibers course obliquely toward the distal ends of the lower three or four (“floating”) ribs. The muscle fibers of the internal oblique fan out following the shape of the iliac crest so that the lowermost fibers are directed inferiorly. These fibers arch over the round ligament, or spermatic cord. Some of the lower muscle bundles in the male join fibers of the transversus abdominis to form the cremaster muscle. The aponeurosis of the internal oblique (Fig. 72-5A) above the level of the umbilicus splits to envelop the rectus abdominis, re-forming in the midline to join and interweave with the fibers of the linea alba. Below the level of the umbilicus (Fig. 72-5B), the aponeurosis does not split but rather runs anterior to the rectus muscle, continues medially as a single sheet, joins the anterior rectus sheath, and finally contributes to the linea alba. The aponeurotic portion of the internal oblique is widest at the level of the umbilicus.

Transversus Abdominis Muscle and Aponeurosis

The transversus abdominis muscle (Figs. 72-2 and 72-3C) arises from the fascia along the iliac crest and inguinal ligament and from the lower six costal cartilages and ribs, where it interdigitates with the lateral diaphragmatic fibers. The muscle bundles of the transversus abdominis for the most part run horizontally. The lower medial fibers, however, may continue in a more inferomedial course toward the site of insertion on the crest and pecten of the pubis.

The aponeurosis of the transversus abdominis joins the posterior lamina of the internal abdominal oblique, forming above the umbilicus a portion of the posterior rectus sheath. Below the umbilicus, the transversus abdominis aponeurosis is a component of the anterior rectus sheath. The gradual termination of aponeurotic tissue on the posterior aspect of the rectus abdominis forms the arcuate line (of Douglas) (Fig. 72-6). The medial aponeurotic fibers of the transversus abdominis insert on the pecten pubis and the crest of the pubis to form the falx inguinalis. These fibers infrequently are joined by a portion of the internal oblique aponeurosis; only then is a true conjoint tendon formed.⁴

The arch formed by the termination of the aponeurotic fibers of the transversus abdominis is called the *aponeurotic arch* (Fig. 72-6). The area beneath the arch varies. A high arch may be a predisposing factor in direct inguinal hernia. Contraction of the transversus abdominis causes the arch to move down toward the inguinal ligament in a kind of shutter mechanism, which reinforces the weakest area of the groin when intra-abdominal pressure is raised.

Figure 72-3. A: External oblique muscle and aponeurosis. B: Internal oblique muscle and aponeurosis. C: Transversus abdominis muscle and aponeurosis. D: Lower rectus abdominis and pyramidalis muscle. The linea alba is formed by the intermeshed fibers of the aponeuroses of the lateral muscle layers; it is tensed by the pyramidalis, which inserts into it.

Rectus Abdominis

The rectus abdominis (Figs. 72-3D and 72-5) forms the central and anchoring muscle mass of the anterior abdomen. The rectus muscle arises from the fifth to the seventh costal cartilages and inserts on the pubic symphysis and pubic crest. Each rectus muscle is segmented by tendinous intersections at the levels of the xiphoid process and the umbilicus and at a point midway between these two. The principal blood supply reaches the muscle from the superior and inferior epigastric arteries (Fig. 72-5), which anastomose just superior to the umbilicus. Other vessels are anterior branches of the intercostal arteries; these reach the muscle by entering the lateral aspect of the rectus sheath. The innervation of the muscle is from the 7th to the 12th intercostal nerves, which laterally pierce the aponeurotic sheath of the muscle. The lateral edge of the muscle is demarcated by a slight depression in the aponeurotic fibers coursing toward the muscle; this depression is the *semilunar line*.

Figure 72-4. Ligamentous structures of the inguinal region. The iliopubic tract is not seen in this view because it is obscured by the inguinal ligament. The lacunar ligament is the expanded medial end of the inguinal ligament; on the pecten pubis, it blends with the inguinal (Cooper) ligament.

The small pyramidalis muscle (Fig. 72-3D) accompanies the rectus abdominis at its origin in a minority of people. The pyramidalis arises from the pubic symphysis. It lies within the rectus sheath and tapers to attach to the linea alba, the conjunction of the two rectus sheaths and the major site of insertion of three aponeuroses from all three lateral muscle layers.

Rectus Sheath

Although the components of the rectus sheath individually have been discussed in relation to the three lateral abdominal muscles, it should also be considered as a distinct entity. Three features of the rectus muscle and its sheath can be observed even topographically in well-muscled or very thin subjects:

1. The semilunar line is a slight depression in the aponeurotic fibers corresponding to the lateral edge of the rectus muscle. It marks the site of initial lateral insertion of the aponeurotic tendons of the lateral abdominal muscles.
2. The tendinous inscriptions divide each muscle into three parts.⁵ These are the basis of the expression “six pack,” popularized by bodybuilders.
3. The linea alba is the midline confluence of the aponeuroses of the rectus muscles and also the internal and external oblique muscles.

Figure 72-5. **A:** Immediately superior to the umbilicus, the rectus sheath consists of anterior and posterior components. The anterior sheath is composed of the aponeuroses of the external and internal abdominal oblique muscles, and the posterior sheath consists of the posterior aponeurotic lamina of the internal oblique and the aponeurosis of the transversus abdominis muscle. **B:** The rectus sheath inferior to the arcuate line (of Douglas) consists of an anterior portion made up of fibers from all aponeurotic layers; the posterior portion at this point comprises only transversalis fascia covered internally by peritoneum.

The composition of the rectus sheath varies depending on the level sampled. The anterior sheath superior to the umbilicus is composed of the aponeurosis of the external abdominal oblique and the anterior lamina of the internal abdominal oblique. The transversalis aponeurosis does not participate in the formation of the anterior sheath at this level. At a variable level inferior to the umbilicus, the anterior sheath is a composite of all the aponeurotic layers.

The posterior sheath of the rectus muscle superior to the umbilicus is a lamination of the posterior lamina of the aponeurosis of the internal abdominal oblique and the transversus abdominis aponeurosis. The external abdominal oblique does not participate in the formation of the posterior portion of the rectus sheath. At a highly variable site inferior to the umbilicus, all the aponeurotic tendons pass anteriorly to form the anterior rectus sheath. The fibers of the posterior sheath are seen to attenuate gradually. The aponeurotic fibers do not end abruptly at the arcuate line. This transfer of connective tissue away from the posterior rectus sheath causes the arcuate line (of Douglas) to form on the posterior surface of the muscle (Fig. 72-6). The tissue covering the deep surface of the rectus muscle inferior to the arcuate line is primarily the transversalis fascia.

Some have questioned this traditional scheme of rectus sheath composition, contending that each of the aponeurotic layers superior to the umbilicus is actually bifid, with both contributing to the anterior and posterior sheaths.⁶ The fibers of the posterior sheath are seen to attenuate gradually. The concept of rectus sheath composition favored by most is shown in Figure 72-7.⁷

Innervation and Blood Supply of the Anterior Abdominal Wall

The innervation of the anterior wall muscles is multiple. The lower intercostal and upper lumbar nerves (T7 to T12, L1, L2) contribute most of the innervation to the lateral muscles, the rectus abdominis, and the overlying skin. The nerves pass anteriorly in a plane between the internal abdominal oblique and the transversus abdominis, eventually piercing the lateral aspect of the rectus sheath to innervate the muscle therein. The external oblique muscle receives branches of the intercostal nerves, which penetrate the internal oblique. The anterior ends of the nerves form part of the cutaneous innervation of the abdominal wall. The first lumbar nerve divides into the ilioinguinal and iliohypogastric nerves. These may divide within the psoas major muscle or between the internal oblique and transversus abdominis muscles. The ilioinguinal nerve may communicate with the iliohypogastric nerve before innervating the internal oblique. The ilioinguinal nerve then passes through the external inguinal ring to run with the spermatic cord, whereas the iliohypogastric nerve pierces the external oblique to innervate the skin above the pubis. The cremaster muscle fibers, which are derived from the internal oblique muscle, are innervated by the genitofemoral nerve (L1, L2).

Figure 72-6. The deep inguinal region, pelvis, and anterior abdominal wall from the viewpoint of a surgeon using a laparoscopic technique. The anterior wall folds upward approximately at the iliopubic tract in this illustration.

Figure 72-7. Patterns of midline decussation of the aponeuroses. **A:** Single anterior and posterior lines of decussation. **B:** Single anterior and triple posterior lines of decussation. **C:** Triple anterior and posterior lines of decussation.

The blood supply of the lateral muscles of the anterior wall is primarily from the lower three or four intercostal arteries, the deep circumflex iliac artery, and the lumbar arteries. The rectus abdominis has a complicated blood supply derived from the superior epigastric artery (a terminal branch of the internal thoracic, or internal mammary, artery), the inferior epigastric artery (a branch of the external iliac artery), and the lower intercostal arteries. The latter arteries enter the sides of the muscle after traveling between the oblique muscles. The superior and inferior epigastric arteries enter the rectus sheath and anastomose near the umbilicus.

Posterolateral (Lumbar) Abdominal Wall

The posterolateral or lumbar portion of the abdominal wall (Fig. 72-8) is often overlooked in discussions of abdominal hernia, perhaps because of the much more common occurrence of groin and femoral hernias. The configuration of the muscle layers in the lumbar area also predisposes to hernia formation. For the purposes of this discussion, the lumbar portion of the abdominal wall is defined as the area bounded superiorly by the 12th rib, inferiorly by the iliac crest, and medially by the erector spinae group. Eight muscles arrayed in three layers constitute the posterolateral or lumbar portion of the abdominal wall.

The most superficial layer is composed of the external abdominal oblique muscle, which arises from the posteroinferior portion of the lower ribs and inserts in part along the posterior iliac crest. Closely associated with the external oblique in this area is the latissimus dorsi, which arises from the posterior iliac crest, the spinous processes of the sacrum and lumbar vertebrae, and the lumbodorsal fascia. The muscle courses obliquely toward its insertion on the medial aspect of the intertubercular groove of the humerus. The triangular space formed by the two muscles just described and the iliac crest is called the *inferior lumbar (Petit) triangle* (Fig. 72-8A).

Figure 72-8. The lumbar abdominal wall with the inferior lumbar triangle (A) and the superior lumbar triangle (B).

The middle layer of lumbar abdominal muscles consists of the erector spinae, the internal abdominal oblique, and the extremely thin insignificant serratus posterior inferior. The erector spinae forms a significant portion of the abdominal wall in the lumbar region, with fibers extending nearly the length of the spinal column. The internal abdominal oblique muscle forms the remainder of the layer. The serratus posterior inferior arises from the lumbodorsal fascia and inserts on the lower four ribs. The middle layer of lumbar muscle is associated with the superior lumbar triangle, a more common site of hernia than the inferior lumbar triangle described previously. The superior triangle (Fig. 72-8B) is formed superiorly by the 12th rib, the serratus posterior inferior, and the superior lumbocostal ligament; inferiorly by the upper border of the internal abdominal oblique; and medially by the erector spinae.

The deep layer of the lumbar abdominal wall includes three muscles: the quadratus lumborum, the psoas major, and the transversus abdominis. The quadratus lumborum primarily arises from the posterior iliac crest and inserts on the 12th rib. The psoas major arises from vertebrae T12 through L5 and passes beneath the inguinal ligament to insert on the lesser trochanter of the femur.

Deep Inguinal Region

Laparoscopic View

Deep Aspect of the Anterior Abdominal Wall, Peritoneal Folds, and Associated Structures. If one creates a space in the abdominal cavity by distending it with gas, an excellent view of the anterior wall can be obtained. The umbilical peritoneal folds (Fig. 72-9) in most subjects are very prominent and provide easily identified landmarks. The folds (ligaments) primarily exist because the peritoneum covers underlying structures.

Figure 72-9. The deep inguinal region and the anterior abdominal wall seen from within the abdomen. The urachus, the obliterated portion of the umbilical artery, and the inferior epigastric vessels are covered by peritoneal folds, respectively called the median, medial, and lateral umbilical folds.

The single median umbilical fold extends from the umbilicus to the urinary bladder and covers the urachus, the fibrous remnant of the fetal allantois. The urachus may be patent for a short distance in adults or may open into the umbilical scar in newborns. The medial umbilical fold is formed by the underlying obliterated portion of the fetal umbilical artery. This normally cordlike structure, like the urachus, may be patent for a portion of its length. Indeed, the proximal, patent portion of the artery normally supplies the superior vesicular arteries to the bladder. The lateral fold covers the inferior epigastric arteries as they course toward the posterior rectus sheath, which they enter approximately at the level of the arcuate line.

Between the median and the medial ligaments, a depression is usually found that is called the *supravesical fossa*. This is the site of hernias of the same name. The fossa formed between the medial and lateral ligaments is the medial fossa; this is the site of direct inguinal hernias. The lateral fossa is less well delineated than the others. The medial border of the fossa is formed by the lateral umbilical ligament and the rectus abdominis. This fossa does not have a lateral border; rather, the concavity slowly attenuates. The deep inguinal ring is located in the lateral fossa and therefore is the site of the congenital or indirect inguinal hernia.

Transversalis Fascia

The transversalis fascia (endoabdominal fascia) is perhaps the most commonly misunderstood structure in the literature devoted to groin hernia. Confusion results because surgeons may actually be referring to very different anatomic structures when discussing various hernia repairs; however, each may use the same anatomic term or eponym. Indeed, perhaps the biggest reservation among surgeons intent on performing a Shouldice repair is a precise definition of what is being sewn to what.

The transversalis fascia proper is a continuous sheet that extends throughout the extraperitoneal space. The term *transversalis fascia* is generally defined as the deep or endoabdominal fascia covering the internal surface of the transversus abdominis, the iliacus, the psoas muscles, and the obturator internus and portions of the periosteum. One variant of this convention is the use of terms specific to the muscle covered by the fascia (e.g., iliac fascia).

Most authors feel that only one layer of transversalis fascia exists, whereas others maintain that the transversalis fascia comprises two layers, or laminae.⁸ The posterior lamina is a layer of fibrous connective tissue that widely varies in density and continuity and is interspersed with adipose tissue, as

seen in [Figure 72-10](#). This layer is often referred to simply as the *preperitoneal fascia*. The anterior lamina is more uniform and is adherent to the deep surface of the transversus abdominis and the rectus abdominis. The posterior lamina is contained within the preperitoneal space, which is defined as the space between the peritoneum and the anterior lamina of the transversalis fascia. The inferior epigastric vessels are enclosed by, or interspersed with, the adipose tissue and the fibrous tissue of the posterior lamina of the transversalis fascia. The vessels are in contact anteriorly with the anterior lamina of the transversalis fascia as they course upward to enter the rectus abdominis sheath.

Transversalis Fascia Derivatives

The transversalis fascia analogs or derivatives are the iliopectineal arch, iliopubic tract, and crura of the deep inguinal ring. The superior and inferior crura form a transversalis fascia sling, a structure shaped like a “monk’s hood,” around the deep inguinal ring ([Fig. 72-9](#)). The transversalis fascia also contributes the internal spermatic fascia to the spermatic cord at this point. This “sling” has functional significance; when the transversus abdominis contracts, the crura of the ring are pulled upward and laterally, which results in a valvular action that helps to prevent the indirect formation of a hernia.

Figure 72-10. A parasagittal section through the layers of the anterior abdominal wall and groin. Observe that the transversalis fascia is depicted as a bilaminar structure.

The iliopubic tract ([Figs. 72-9](#) and [72-11](#)) has become an increasingly important landmark for surgeons as the use of laparoscopic technology has increased.^{9,10} The iliopubic tract is the thickened band of transversalis fascia formed at the zone of transition between the deep surfaces of the iliac and transversus abdominis muscles. The structure courses parallel to the more superficially located inguinal ligament, is attached to the iliac crest laterally, and inserts on the pubic tubercle medially. The tract forms along its course a portion of the inferior crus of the deep inguinal ring and then contributes to the anterior and medial walls of the femoral sheath. The tract fuses with the inguinal ligament to form a component of the inferior wall of the inguinal canal. At its insertion on the pubic tubercle, it curves backward slightly to blend with the Cooper pectineal ligament. The pectineal ligament is actually a condensation of periosteum and is not a true analog of the transversalis fascia, but it is reinforced by fibers from the iliopubic tract and inguinal ligament.

Figure 72-11. A schematic representation of the deep inguinal region. The iliopubic tract is shown as a thickening of the transversalis fascia, inferior to which many of the branches of the lumbar plexus exit the pelvis.

The iliopubic tract contains not only fibrous connective tissue but also some elastic fibers.¹¹ In one series, the iliopubic tract was a substantial structure, suitable for use in hernia repairs, in 42% of the specimens examined. The tract, whether substantial or not, can be used as a readily identified landmark.

The iliopubic tract has particular significance because of its importance as a landmark to the laparoscopic surgeon. Many of the branches of the lumbar plexus run inferior to the tract, and damage to these nerves may be the result of aggressive dissection or the placement of tacks or staples to affix a prosthesis below this structure. The tract is not obviously visible in every patient from a laparoscopic view, but its location should always be immediately known to the surgeon because of its constant relationship to the other landmarks in this area.

The iliopectineal arch (Fig. 72-9) is also a condensation of the transversalis fascia. The iliopectineal arch commences at the medial border of the iliacus muscle, where it is continuous with the iliac fascia, itself a portion of the transversalis (endoabdominal) fascia. The arch separates the vascular compartment containing the femoral vessels from the neuromuscular compartment containing the iliopsoas muscle, femoral nerve, and lateral femoral cutaneous nerve. The iliopectineal arch also contributes to the proximal portion of the femoral sheath, thereby joining the iliopubic tract in the formation of the femoral sheath.

Femoral Sheath, Canal, and Ring

The femoral sheath (Fig. 72-12) is primarily composed of extensions of the transversalis fascia. The sheath is best understood in terms of the structures contained within. As the external iliac artery and vein pass beneath the inguinal ligament to become the femoral vessels, they are covered anteriorly by the transversalis fascia proper. This fascial layer is posteriorly and laterally joined by portions of the iliopsoas fascia, which themselves are continuations of the transversalis fascia. At the inguinal ligament, the iliopsoas fascia forms the iliopectineal arch. This arch divides the vascular compartment (lacuna vasorum), containing the femoral vessels, from the muscular portion (lacuna musculorum), which contains the iliopsoas muscle, femoral nerve, and lateral femoral cutaneous nerve. The vascular lacuna is further divided by septa into compartments for the vessels and the femoral branch of the genitofemoral nerve.

Figure 72-12. Schematic view of the femoral sheath, ring, and canal. The transversalis fascia forms the anterior portion of the sheath, and the iliopsoas fascia forms the posterior portion. Septae separate the vessels from each other and the vein from the femoral canal. The femoral ring contains a lymph node. The ring is formed medially by the aponeurosis of the transversus abdominis aponeurosis, anteriorly by the inguinal ligament, posteriorly by the pubic bone, and laterally by the femoral sheath.

The medial border of the femoral sheath follows the transversus abdominis aponeurosis to its insertion just lateral to that of the lacunar ligament and extends inferiorly to fuse eventually with the medial septum and adventitia of the femoral vein. The resultant cone-shaped cul-de-sac is the femoral canal. The canal normally contains only wisps of connective tissue and small lymphatic nodes. The wider proximal part of the canal, the femoral ring, contains a large node, which is often referred to as the *Cloquet node*.

The femoral ring is the extraperitoneal opening of the canal. The boundaries of the ring are formed medially by the curved edge of the transversus abdominis aponeurosis, not the lacunar ligament, which inserts more medially.¹² Laterally, the ring is bounded by the connective tissue septum and the adventitia that is interposed between it and the femoral vein. The anterior boundary is the inguinal ligament; posteriorly, the ring is reinforced by the iliopubic tract and iliopectineal ligament. The canal is not in direct communication with the pelvic cavity. The transversalis fascia is not a component of the roof of the canal because it is diverted at this point to form the femoral sheath. This weakened area is therefore quite prone to hernia formation, especially in female subjects.

Inguinal (Hesselbach) Triangle

The inguinal triangle is the site of direct inguinal hernias. This triangle is most often described from the anterior aspect (Fig. 72-13), in which case the inguinal ligament forms the base of the triangle, the rectus abdominis forms the medial border, and the inferior epigastric vessels form the superolateral border. The triangle as originally described by Hesselbach had the pectineal ligament as its base. The latter description is quite useful to the surgeon viewing the abdomen from within because the inguinal ligament cannot be seen from this viewpoint. When the inguinal triangle is transilluminated, the thinness and translucency of the area of abdominal wall within the triangle underscores its importance in hernia development and repair. In the most translucent area, little or no muscle is present. Only the peritoneum and the transversalis fascia cover the triangle here. The aponeurotic arch of the transversus abdominis crosses the triangle just below the apex in most people. A high aponeurotic arch affords less reinforcement to the triangle and may therefore predispose a person to the formation of a direct inguinal hernia.

Components of the Spermatic Cord

The spermatic cord (Figs. 72-11 and 72-14) is closely associated with the deep inguinal ring. The spermatic cord is most appropriately described at this point because the deep ring itself is formed by derivatives of transversalis fascia, as is the innermost covering layer of the spermatic cord, the internal spermatic fascia. The middle covering layer is called the *cremasteric fascia* and contains the cremasteric muscle bundles; both are derived from the internal abdominal oblique muscle and fascia. The outermost covering of the spermatic cord is the external spermatic fascia, which is continuous with the investing fascia of the external abdominal oblique muscle.

The tunica vaginalis is initially a component of the cord, but normally it atrophies and closes early in neonatal life. This structure is an evagination of peritoneum. The testicle descends retroperitoneally in

fetal life and is merely in contact with the posterior aspect of the tunica. An indirect congenital hernia enters the patent tunica vaginalis.

Figure 72-13. The inguinal (Hesselbach) triangle.

Figure 72-14. The component layers covering the contents of the spermatic cord.

The cord structures enclosed by the coverings described earlier are the ductus (vas) deferens, the pampiniform venous plexus, the testicular artery, and the genital branch of the genitofemoral nerve, a branch of the lumbar plexus (Figs. 72-9, 72-11, and 72-15).

Branches of the Lumbar Plexus

The nerves crossing the iliac fossa are some of the most variable in the body. This variability may be the cause of frequent intraoperative injury to the fragile nerves. The lumbar plexus is formed by roots from the 12th thoracic nerve and the first through fourth lumbar nerves. Cutaneous territories innervated by branches of the lumbar plexus are seen in Figure 72-15A. The five terminal branches commonly encountered in laparoscopic herniorrhaphy can be discerned in many people as they course across the iliacus muscle covered by peritoneum and the iliac fascia (a portion of the transversalis-endopelvic fascia). The nerves form within or deep to the psoas major muscle (Fig. 72-15B), often ramifying with other nerves within or close to the muscle. The nerve branches initially lie within the so-called triangle of pain,¹³ bordered medially by the psoas muscle, anteriorly and inferiorly by the iliopubic tract, and laterally by the iliac crest. With the exception of the genital branch of the genitofemoral nerve, the branches of the lumbar plexus destined for the thigh run beneath the iliopubic tract.

Figure 72-15. A: The cutaneous territories innervated by several branches of the lumbar plexus. B: Some of the branches of the lumbar plexus seen from within the abdomen.

The most anterior of the nerves encountered, the genitofemoral nerve, is also the most variable. This nerve may occur as a single trunk lying deep to the peritoneum and fascia on the anterior surface of the psoas muscle. The nerve may also divide into its component genital and femoral branches within the muscle. The genital branch travels with the spermatic cord, entering at the deep inguinal ring; it ultimately innervates the cremaster muscle and the lateral scrotum. The femoral branch of the nerve innervates the skin of the proximal mid-thigh.

The lumbar plexus branch encountered immediately deep to the lateral aspect of the psoas muscle is the large femoral nerve. Although not routinely encountered during laparoscopy, the femoral nerve has been injured in some cases.¹⁴ The lateral femoral cutaneous nerve crosses the iliac fossa under the iliac fascia to run deep to the iliopubic tract and the inguinal ligament, which it pierces to enter the thigh.

The iliohypogastric nerve typically arises with the ilioinguinal by a common trunk from the first lumbar nerve. They may exchange fibers within the muscle, but they usually diverge immediately to form individual nerves. The iliohypogastric nerve crosses the iliac fossa just inferior to the kidney and pierces the transversus abdominis. The subsequent course of the nerve carries it between the transversus and the internal abdominal oblique until it pierces the aponeuroses of both obliques just above the external inguinal ring.

The ilioinguinal nerve normally crosses the iliac fossa just inferior to the iliohypogastric nerve. In its typical further course, the nerve pierces the transversus abdominis and internal abdominal oblique above the iliac crest and eventually enters the inguinal canal. The nerve may run more diagonally through the iliac fossa and then pierce the iliopubic tract to reach the inguinal canal.¹⁵ This path “can obviously render the nerve more vulnerable to iatrogenic injury.”

Vasculature of the Abdominal Wall and Deep Inguinal Region

The vasculature of the deep inguinal region and anterior abdominal wall has been analyzed by surgeons for well over 100 years. The importance and variability of these vessels have been underscored by the ominous mnemonics used to refer to them – “crown of death” (*corona mortis*) and “triangle of doom.” The primary blood supply to the deep anterior wall is from the inferior epigastric artery. This artery is a branch of the external iliac artery. In many cases, an artery called the “aberrant” obturator artery arises from the inferior epigastric, which joins the “normal” obturator artery and thereby forms a circle – the

corona mortis – before entering the obturator foramen. Injury to the circle, usually sustained while the surgeon is working in the area of the Cooper ligament, causes copious bleeding. Recent studies have indicated that aberrant obturator vessels are present in between 60% and 90% of the whole pelvis studied.^{16,17}

The veins in this area are also prone to injury because many, especially the iliopubic veins and obturator veins and their tributaries, may be much larger than their accompanying arteries. One network of veins in the area is situated on the inferior deep surface of the rectus muscles. The veins of this network, which anastomose with the pubic branches discussed earlier, have been called the *rectusial veins*.¹⁸

The vessels in the vascular compartment of the deep inguinal region are the external iliac artery and vein. They arise within a triangular area bordered laterally by the gonadal vessels and medially by the ductus deferens. The primary continuations of the external iliac vessels are the femoral artery and vein. The inferior epigastric artery is a branch of the external iliac. The obturator artery may arise from either of these arteries as a replacement or accessory to the obturator branch of the internal iliac artery.

A final vessel to consider in this review is the deep circumflex iliac artery (Fig. 72-10). The origin of this artery is extremely variable, but its course is predictable along the iliopubic tract. It pierces the transversalis fascia and runs along the iliac fossa to anastomose eventually with a deep lumbar artery. Because the deep circumflex artery runs along the iliopubic tract, it can inadvertently be stapled or otherwise injured during laparoscopic herniorrhaphy.

Pelvic Floor and Obturator Muscles

The pelvic musculature normally affords remarkable support to the structures within the true pelvis. Although a myoaponeurotic hammock-like sheet forms the pelvic diaphragm, obturator muscles and membrane, and urogenital diaphragm, herniation of fat or viscera through or around any of these layers occurs. The potential for hernia formation is increased because of the openings through which many structures exit or enter the pelvis.

The Latin term *obturator* is translated as “stopper for a bottle.” The aptly named obturator internus, along with its membrane and the obturator externus, closes off nearly all the large obturator foramen. The small superolateral aperture through which the obturator vessels and nerve pass is the site where obturator hernias form. The obturator internus arises from the deep surface of parts of all three pelvic bones. The muscle fibers converge on a tendon, which leaves the pelvis through the lesser sciatic foramen to insert on the greater trochanter. The dense internal obturator fascia covers the muscle and is thickened to form the arcuate ligament, from which the levator ani muscles (the pelvic diaphragm) are in part suspended. The obturator internus fascia splits to enclose the pudendal vessels in the pudendal canal. The external obturator muscle arises from the pelvic bones surrounding the obturator foramen and from the anterior portion of the obturator membrane. The external obturator muscle is supplied by the obturator nerve and vessels.

The component muscles of the bowl-shaped pelvic diaphragm, the pubococcygeus, iliococcygeus, and puborectalis, along with the coccygeus form the floor of the pelvis. The pubococcygeus arises from the posterior aspect of the pubis and the thickened portion of the internal obturator fascia, called the *tendinous arch* (Fig. 72-16), that spans the distance between the pubis and ischial spine. The puborectalis, the midportion of the diaphragm, arises from the pubis and loops around the rectum as the puborectal sling. The iliococcygeus is suspended at its origin from the tendinous arch and inserts on the coccyx. The coccygeus muscle completes the diaphragm posteriorly, arising from the ischial spine and inserting on the sides of the coccyx.

The area remaining between the sacrum and the greater sciatic foramen is filled for the most part by the piriformis muscle. The piriformis arises from the anterior surface of the second through fourth sacral vertebrae and the sacrotuberous ligament. This muscle exits the pelvis through the greater sciatic foramen, which is thereby divided into suprapiriform and infrapiriform portions (Figs. 72-16 and 72-17). The superior gluteal nerves and vessels pass through the suprapiriform foramen, whereas the inferior gluteal nerves and vessels in company with the sciatic nerve pass through the infrapiriform foramen.

The most pronounced deficit in the pelvic diaphragm is situated anteriorly, where an aperture must allow the urogenital structures to pass out of the pelvis. This area is reinforced by the urogenital diaphragm, a structure primarily consisting of the superficial and deep transverse perineal muscles. The deep transverse perineal muscle is enclosed by a weak superior fascia and a sturdier inferior perineal fascia. The urogenital diaphragm recently has been shown to be more funnel shaped than sandwichlike,

as previously depicted in many atlases. The urogenital diaphragm exists only in humans because the human pelvic outlet faces inferiorly, unlike that of quadrupeds.

Figure 72-16. A: The pelvic diaphragm (levator ani and the piriformis) and the urogenital diaphragm viewed from within the pelvis. B: Hemisection of the pelvis revealing the levator ani, piriformis, obturator internus, and psoas muscles.

WHY DO HUMAN BEINGS DEVELOP ABDOMINAL WALL HERNIAS?

2 The most common hernias develop at sites where the abdominal wall has natural openings such as the internal inguinal ring, the umbilicus, and the esophageal hiatus. Previous surgical entry sites (incisional hernia) are also common areas where hernias develop. Factors that increase the pressure in the abdominal cavity, such as obesity, heavy lifting, coughing with chronic lung disease, straining during a bowel movement or urination (prostatism), chronic lung disease, and ascites, have traditionally been considered important in the etiology, especially at these natural openings. Developmental phenomena also play a role. For example, in the evolution from a quadruped to a biped, the unprotected groin is more vulnerable to changes in intra-abdominal pressure, predisposing to inguinal herniation. Major risk factors for the development of an abdominal wall hernias include chronic obstructive pulmonary disease, smoking, high intra-abdominal pressure, collagen vascular disease, thoracic or abdominal aortic aneurysm, peritoneal dialysis, matrix metalloproteinase (MMP) abnormalities, and an increased type I: type III collagen ratio.

The role of heavy lifting, especially a single strenuous event, is an unsettled question and has considerable medical–legal ramifications. There is minimal evidence that vigorous abdominal wall activity is an independent risk factor for abdominal wall hernia development despite the overwhelming opinion to the contrary in the lay literature.^{19–21} In a systematic review of existing evidence performed

by Svendsen and colleagues, regarding the effects of occupational and mechanical exposures in relation to inguinal hernias, a causal relationship could not be established between specific mechanical insults and occurrence of inguinal hernia, hernia recurrence, and persistent pain after inguinal hernia repair.^{22,23} According to the results of another register-based male cohort study in Denmark, increasing cumulative exposure to daily lifting activities and prolonged standing or walking at work was associated with an increased risk of having an indirect inguinal hernia repair.^{22,23} The authors hypothesized that patent processus vaginalis may be more susceptible to changes in intra-abdominal pressures, whereas in a direct hernia, other mechanisms may be involved in connective tissue degradation and weakening of the transversalis fascia. Still, the role of mechanical activity in the development of abdominal wall hernia is not completely clear, and further research is needed to determine if inguinal hernias can be prevented and if the postoperative prognosis can be improved by reducing occupational mechanical exposures.

Figure 72-17. The gluteal muscles and lateral rotators of the hip. External relations of the sciatic foramen are also evident.

Familial predisposition and the role of connective tissue diseases in hernia development have received considerable attention in recent years. Particularly important for inguinal hernia is a family history as it has been reported to increase the risk up to 8 times.^{24,25} Various connective tissue disorders, such as osteogenesis imperfecta, Marfan syndrome, Ehlers–Danlos syndrome, and congenital hip dislocation, are associated with hernias. Imbalances in collagen, the basic building block of the abdominal wall, are believed to contribute to hernia disease. While type I collagen confers predominantly tensile strength, type III collagen consists of thinner fibers and is regarded as a temporary matrix during tissue remodeling. A decreased ratio of type I to type III collagens can be detected in fascial and skin specimens obtained from patients with hernias. A similar phenomenon was discovered by Cannon and Read in smokers when they performed biopsies of the rectus sheaths from adult smokers with inguinal hernias and coined the term “metastatic emphysema.”²⁶ The investigators also demonstrated significantly greater levels of circulating serum elastolytic activity in patients who smoke.

Aside from primary defects in collagen synthesis, the imbalances in collagen in patients with hernia can be attributed to altered extracellular matrix (ECM) which is maintained in a dynamic balance of synthesis and degradation by a complex set of enzymes. MMPs,²⁷ which are a group of 23 structurally related zinc-dependent enzymes, protease with collagenolytic activity and have a pivotal role in the integrity and composition of the ECM.

The association between MMP overexpression and abdominal wall hernia was initially demonstrated by Bellon and colleagues, who studied the expression of MMP-1 and MMP-2 in the transversalis fascia of patients with direct and indirect inguinal hernia. Since then, several studies have been conducted, aiming at elucidating the role of MMPs in the development of primary and recurrent abdominal wall

hernias. For this purpose, MMP levels in fascia, skin, hernia sac, and blood specimens of patients with inguinal, incisional, and recurrent abdominal wall hernias have been measured. The expression of MMP mRNA in cultured fibroblasts has also been investigated to evaluate cell–cell and cell–matrix interactive mechanisms as causative factors for abnormal MMP production. In addition to this, in-vitro studies have been performed to study the effect of different mesh materials on MMP expression on cultured fibroblasts; in one such study, polypropylene has been shown to induce less MMP2 expression than polygalactin. The function of MMPs is further regulated by a variety of endogenous regulators, the most important ones are known as tissue inhibitors of MMPs (TIMPs).^{28–30} Studies have shown that an imbalance between MMP and TIMP activity may have a role pathogenesis of abdominal wall hernias.³¹

Despite the increasing knowledge regarding MMPs in incisional and inguinal hernia, the exact role of MMPs in the pathogenesis of hernia formation remains unclear. Most studies are small and not completely controlled; and there is a remarkable heterogeneity among studies concerning the characteristics of the study populations, the examined tissue specimens, and the biochemical assays used. In addition to MMP and TIMPs, factors that have been implicated in hernia development include deficiency of the elastic fiber system of the transversalis fascia, decreased tropoelastin and lysyl oxidase-like 1 synthesis, elastase overexpression and TGF-beta1 overexpression. It remains unclear whether these alterations in hernia patients are a part of the “cause or effect” phenomenon. Another interesting area of research are drug classes that can suppress MMP expression (e.g., tetracyclines, especially doxycycline, aspirin, statins, and thiazolidinediones) and understanding their role in hernia prevention and treatment.³²

Figure 72-18. Reduction of a hernia by taxis. **A:** Applying pressure on the hernia directly occludes the neck. **B:** Elongating the neck of the hernia while applying pressure allows reduction.

COMPLICATIONS OF HERNIAS

Hernia Accident

For years, surgeons have been taught that all hernias should be repaired at diagnosis to prevent a hernia accident, which is defined as a bowel obstruction or incarceration with strangulation, because of the perception that patients presenting with these complications have an unacceptable increase in mortality. This thinking, however, has not stood up when tested in randomized controlled trials. For example, for men with asymptomatic inguinal hernias, randomized controlled trials have shown that a strategy of watchful waiting is safe.³³

Incarceration

Incarcerated means “trapped” or “imprisoned.” Clinically, an incarcerated hernia is an irreducible hernia. An incarceration is not in and of itself a surgical emergency. Many hernias are chronically incarcerated due to adhesions of contents (e.g., omentum, bowel, ovary, etc.) to the hernia sac. The hernia itself is not necessarily tense to palpation, and the overlying skin appears normal. Normal bowel sounds may be heard within the hernia. It is important to differentiate an incarcerated hernia from a hydrocele of the cord. One can get above the hydrocele with the examining fingers. One cannot get above a hernia, however, as it communicates with the abdominal cavity. Hydroceles will transilluminate clearly, but a hernia will not.

An acutely incarcerated, painful hernia must be managed carefully. An attempt at reduction is reasonable unless there are signs of strangulation, which is not always obvious by clinical examination.

Immediate surgical exploration is the safest approach when the diagnosis is not clear. The advantage of reduction followed by elective repair is that edematous tissue associated with an acute incarceration can return to normal, which presumably will translate into a better repair with less chance of infection.³⁴ If an attempt at reduction seems reasonable, the patient is sedated and placed in bed. The Trendelenburg position should facilitate reduction of a groin hernia. An attempt should be made at the initial examination to reduce the hernia. The maneuver of taxis entails grasping the neck of the hernia with the fingers of one hand and then applying intermittent pressure on the most distal part of the hernia with the other hand. Taxis has the effect of elongating the neck of the hernia so that the contents of the hernia may be guided through this area back into the abdominal cavity with a rocking movement. Mere pressure on the most distal part of the hernia causes bulging of the hernial sac around the neck, which can occlude the neck and prevent it from being reduced (Fig. 72-18). The maneuver of taxis should not be performed with excessive pressure or too vigorously. If the hernia is strangulated, gangrenous bowel might be reduced into the abdomen or perforated in the process. One or two gentle attempts should be made at taxis. If they are unsuccessful, this procedure should be abandoned. Rarely, the hernia together with its peritoneal sac and constricting neck may be reduced into the abdomen (reduction en masse). The patient would then have persistent obstruction after reduction of the hernia.

Intestinal Obstruction

One hundred years ago, the most common cause of intestinal obstruction was a hernia. At the present time, hernia is third, after adhesive obstructions and cancer. Hernia is an important cause of obstruction that is not infrequently missed on clinical examination. When a patient with an intestinal obstruction is examined, great emphasis should be placed on adequate exposure of the entire abdominal wall and groin area (from nipples to knees). Proper lighting is essential because previous scars can fade with time and become barely perceptible. The patient with intestinal obstruction as a result of a hernia will have a tense hernia that is irreducible. The abdomen itself will be distended, and high-pitched bowel sounds with frequent rushes will be heard. If the process continues to the complication of strangulation, these signs will disappear. Unlike adhesive small-bowel obstructions, partial small-bowel obstructions secondary to hernia are rare. Most patients will have had vomiting and obstipation.

A plain roentgenogram of the abdomen will reveal the signs of an intestinal obstruction – dilated loops of bowel with air–fluid levels and no bowel gas distal to the obstruction. Frequently on a plain roentgenogram, one can see bowel shadows in the region of the hernia. A lateral view is often useful to demonstrate this feature more clearly. Contrast studies are not usually necessary in this instance. Computed tomography (CT) reliably demonstrates the hernia with characteristic features of obstruction and should be considered if the clinical diagnosis is not certain (Fig. 72-19) because a distal intestinal obstruction secondary to another cause (e.g., adhesions) may result in significant distention of a coincidental nonobstructing hernia of the abdominal wall. Should the examiner focus attention exclusively on the hernia, the real cause of the obstruction may be missed when the hernia is repaired.

Figure 72-19. Computed tomogram showing a left-sided inguinal hernia.

Figure 72-20. Richter hernia. Part of the bowel wall herniates through the defect in the abdominal wall.

The next steps in management include resuscitation followed by urgent surgery. At surgery, an approach directly over the hernia is used. In all patients, the entire gastrointestinal tract must be assessed to eliminate causes of obstruction other than the hernia itself. This is done before the hernia is repaired. The bowel, if viable, is reduced into the abdomen. If difficulty is encountered in reducing the hernia, the neck of the hernia can be widened. In the case of an inguinal hernia, division of the neck with or without ligation and division of the inferior epigastric vessels is safe, and the hernia contents can be reduced into the abdomen. In the case of a femoral hernia, the inguinal ligament can be split anteriorly and the hernia contents reduced into the abdomen. If the bowel is nonviable, then a bowel resection can be performed with anastomosis. The hernia is then repaired.

Strangulation

Strangulation of a hernia is a serious and life-threatening condition in which the hernia contents become ischemic and nonviable. The pathogenesis of this condition involves intra-abdominal contents within the hernia sac. Straining may push more contents into the sac, and the tense sac then causes pressure at the neck. This pressure initially produces venous congestion, resulting in edema. Eventually, the pressure is so great that the arterial supply is obstructed and the contents become gangrenous.

When intestine is involved, in addition to having an irreducible hernia and intestinal obstruction, the patient is toxic, dehydrated, and febrile. Examination of the abdomen reveals the signs of an intestinal obstruction, with distention and increased bowel sounds. Absolute constipation and vomiting are other manifestations. The hernia itself is tense, irreducible, and very tender, and the overlying skin may be discolored with a reddish or bluish tinge. No bowel sounds are heard within the hernia itself. The patient commonly manifests a leukocytosis with a predominance of polymorphonuclear leukocytes. Blood gases may reveal metabolic acidosis.

Management of these patients requires urgent attention to detail. No attempt should be made to reduce the hernia. Rapid resuscitation should commence immediately, with nasogastric suction and replacement of fluids and electrolytes. The patient should be given antibiotics. Once the patient is resuscitated, urgent surgery commences to expose the hernia, open the sac, and assess the viability of the bowel. More bowel can be pulled into the hernia so that viable bowel can be transected and the gangrenous portion removed. An end-to-end anastomosis should be performed and the bowel then reduced into the abdominal cavity. The hernia is then repaired.

Richter Hernia

August Gottlieb Richter in 1785 described a hernia type that bears his name in which the antimesenteric border of the intestine protrudes into the hernia sac without involving the entire circumference of the intestine so that intestinal obstruction does not occur ([Fig. 72-20](#)). The most common site is the femoral ring (36% to 88%), followed by the inguinal canal (12% to 36%), and an abdominal wall incision (4% to 25%). Miscellaneous locations include umbilical, obturator, supravesical, Spigelian, triangle of Petit, sacral foramen, Morgagni, internal, and diaphragmatic.³⁵ The routine use of laparoscopy by general surgeons has resulted in an increased incidence at trocar sites such that most surgeons will repair the fascia for trocar sleeves greater than 5 mm. The surgical treatment is to expose the herniated bowel by opening the sac. The neck of the sac is enlarged to allow delivery of the bowel into the wound. Any areas of gangrene are excised and the bowel wall reconstituted. The hernia is then repaired.

Prosthetic Materials

The development of a wide variety of materials for abdominal wall reconstruction makes it possible to individualize the selection of prostheses so that they can be used in almost all clinical situations. Currently available prosthetic materials can be divided into synthetic or biologic depending on their source. The synthetic prostheses can be further classified as noncomposite heavyweight plastic, noncomposite heavyweight membrane, noncomposite lightweight plastic, composite, and coated prosthesis. Although surgeons use the term mesh to refer to all varieties of hernia prostheses, this is inaccurate as only prostheses that have large grossly visible interstices should be termed meshes. Microporous material such as expanded polytetrafluoroethylene (ePTFE) have no visible interstices, do not promote ingrowth as with the mesh prosthesis, and act more like a membrane. In the absence of infection, synthetic material is preferred to biologic prostheses. The materials that have the longest track record for routine use in hernia surgery include polyester, polypropylene, either monofilament (Marlex, Prolene) or polyfilament (Surgipro); Dacron (Mersilene); and ePTFE (Gore-Tex). Synthetic materials such as polypropylene or polyester work by inciting an intense fibroplastic response to form a strong scar plate interface. Because of this response, they should not be used adjacent to the viscera because of the propensity of these materials to erode into intra-abdominal organs, most commonly intestine, resulting in fistulization. The weight of the polypropylene or polyester meshes, as well as the size of the pores, is a controversial issue currently. As an example, a 7.5- × 15-cm polypropylene mesh (Prolene, Ethicon, Inc.) contains about 80 g/m² of polypropylene, while a polypropylene–poliglecaprone-25 (Monocryl) lightweight mesh of the same size (UltraPro, Ethicon, Inc.) contains less than 30 g/m². One of the ways of reducing the amount of nonabsorbable material in a mesh is to increase the size of the pores. Many authorities believe that the inflammatory response incited by the small-pore, heavyweight plastic meshes can lead to chronic pain; a sensation of being able to feel the mesh; increased stiffness of the abdominal wall with loss of compliance; and shrinkage, which can lead to recurrence. There is increasing evidence that decreasing the density of polypropylene and increasing the size of the pores reduces this foreign body response, resulting in less long-term pain than normal mesh with a similar recurrence rate.^{36–39} Recently, there have been reports of “burst mesh” or central mesh failures with the use of lightweight mesh in the repair of large ventral hernias and thus, one should exercise caution while employing them in repair of massive hernias.⁴⁰

Table 72-2 Classification and Examples of Prosthetic Materials Currently Available for Hernia Repair

Noncomposite			Composite	Coated	Absorbable	Biologic
Heavyweight Plastic	Heavyweight Membrane	Lightweight Plastic				
Ethicon Prolene™ Mesh (PPL)	Gore Soft Tissue Patch™ (ePTFE)	Ethicon Ultrapro™ (PPL + poliglecaprone 25)	Bard Composix™ EX & LP (Polypropylene + ePTFE)	Atrium c-Qur™ (PPL + Omega-3-fatty acid)	Phasix™ Mesh (Poly-4-Hydroxybutyrate P4HB)	AlloDerm™ (Cadaveric Human skin)
Dacron™ Polyester mesh	Gore Mycromesh™ (ePTFE)	Atrium Prolite ultra™	Bard Ventralex™ (PPL + ePTFE + PPL tail)	Symbotex™ Composite Mesh Covidien monofilament polyester (PET) A bioabsorbable collagen film	TIGR™ Mesh	Strattice™ Porcine acellular dermal matrix
Prolene hernia system (PHS)™ Ethicon (PPL)	GoreTex™ (ePTFE)	Parietex™ Lightweight (Polyester)	Bard Kugel™ Hernia Patch (PPL + ePTFE + PPL ring)	Gore DualMesh™ Plus (ePTFE + silver + chlorhexidine)	BioA™ Mesh	Surgisis™ Porcine submucosa
Ethicon Prolene™ soft Mesh (PPL)	Gore Infit™ mesh (knitted PTFE)		Ethicon Physiomes™ Flexible Composite Mesh	Bard Sepramesh™ (PPL + hydrogel barrier)	VICRYL™ (polyglactin 910) Woven Mesh	AlloMax™ Human collagen matrix
PROLENE™ 3D Patch PPL Mesh	Bard Dulex™ mesh			VENTRALIGHT™ ST Mesh Lightweight PPL + hydrogel barrier		Permacol Porcine dermal matrix
Covidien Surgipro™ Flat Sheet Mesh (PPL)				Ethicon Proceed™ (PPL + PDS + ORC)		PeriGuard™ Bovine pericardium with glutaraldehyde
Marlex™ (PPL)				Covidien Parietene™ (PPL + hydrophilic collagen) Covidien Parietex™ (POL + hydrophilic collagen) Bard Ventrion™ ST patch (PPL + hydrogel barrier) Parietex™ Optimized Composite (PCOx) Mesh (Polyester + Collagen)		Veritas™ Bovine pericardium FlexHD™ Human allograft skin SurgiMend™ Fetal bovine dermal collagen

When contact of mesh with viscera cannot be avoided, either a nonmesh material such as ePTFE alone or a dual-layered prosthesis with a standard plastic mesh on the side facing the abdominal wall and ePTFE facing the viscera should be used. Because ePTFE heals by encapsulation rather than

incorporation as with the mesh prostheses, it does not have the propensity to erode or fistulize which makes it suitable for use adjacent to abdominal viscera. This lack of incorporation has a downside in terms of increased susceptibility of ePTFE to infection, and when these do get infected, they almost always have to be removed. On the other hand, the incorporated mesh materials such as polypropylene can commonly be salvaged when infected. To address this issue, manufacturers have developed temporary or biodegradable adhesion barrier materials to coat the mesh on the side facing the viscera to prevent adhesions without the need for ePTFE (Table 72-2). The injured peritoneum forms a mesothelial layer as quickly as 5 to 7 days with the adhesion barrier products being degraded over the course of an average of 30 (range 28 to 240) days.⁴¹ Neither the adhesion barriers nor ePTFE can completely eliminate adhesions. Patients who undergo laparotomy after either type of prosthesis has been placed intra-abdominally are routinely found to have significant adhesions to the device. However, these adhesions tend to be filmy and easily taken down. It remains to be seen if the long-term performance of coated prostheses compares to ePTFE with its long track record.

The role of biologic tissue matrix in ventral hernia repair has evolved over the last few years. These materials are derived from human, porcine, or fetal bovine skin; porcine small intestine submucosa; and bovine pericardium and are processed to remove hair, cells, and cell components as well as other antigens present in the matrix, leaving only the highly organized collagen architecture with the surrounding extracellular ground tissue.³² The matrix acts as a scaffold to allow native tissue and neovascularization to infiltrate the healing wound and promote strong tissue in-growth that limits contraction. These properties, theoretically, lead to increased resistance to infection. Some biologics undergo further processing to increase the crosslinking between collagen fibers and to decrease susceptibility to degradation by collagenase. In general, these materials possess the physical and mechanical characteristics of a clinically acceptable surgical mesh in that have sufficient mechanical strength to withstand the physiologic and anatomic stresses of the abdominal wall.⁴²⁻⁴⁴

Because of the properties mentioned above, it is felt by some surgeons that the best indication for biologic prostheses is in contaminated wounds, where a synthetic prosthesis may be contraindicated. They are not useful in grossly infected wounds presumably because of the high collagenase content present, which destroys them. It should be noted that none of the biologic prostheses are regulated by the U.S. Food and Drug Administration (FDA) as a medical device and are typically approved under a 510 (K) approval process which is primarily based on safety. These materials were introduced into clinical practice and used in contaminated fields without prior FDA approval or clearance for this indication.⁴⁵ Another major argument against them is their expense, as they generally cost 20 to 30 times that of the plastic prostheses. The majority of evidence for the use of biologic prostheses for hernia repair is based on retrospective studies and mostly in clean procedures. Pooled results from 635 patients treated with three different biologic materials have revealed a recurrence rate of up to 18% to 30% at 2 years with biologic prostheses.^{43,45} Retrospective study with long-term follow-up (>5 years) with the use of porcine acellular dermal matrix for repair of incisional hernias *at risk for infection* showed a recurrence rate of 20% and 53% when used as an onlay or intraperitoneal sublay technique compared to 80% when used as a bridge in either inlay or sublay position, with particularly high recurrence rates seen in contaminated (71%) and grossly infected (100%) wounds.⁴⁶ Although these materials allow a single stage repair of hernias in a contaminated field, with no or little need for mesh removal in case of subsequent wound infection, the high rate of recurrence with the use of biologics, especially in contaminated fields, remains a concern.

A major factor in the popularity of biologic materials for hernia repair is reluctance among many surgeons regarding the use of synthetic mesh in clean-contaminated and contaminated fields, although currently available evidence does not support this view. A retrospective review evaluating lightweight polypropylene mesh placed in a sublay position, in clean-contaminated and contaminated cases revealed a 14% surgical site infection rate (7.1% for clean-contaminated and 34% for contaminated cases) and a 7% recurrence rate at a mean follow-up of 10 months.⁴⁷ Results from this and other similar experiences challenge the surgical dictum contraindicated in a contaminated surgical field. Even when infectious complications occur, synthetic macroporous mesh materials can often be salvaged without the need for removal.

Another interesting area of research is development of novel materials which integrate the desirable qualities of both biologic and synthetic mesh materials. Examples of such materials include Phasix® mesh (Davol, Warwick RI) which is a long-term resorbable mesh composed of monofilament poly-4-hydroxybutyrate, TIGR Matrix Surgical Mesh® (Novus Scientific) which is composed of fast and slow degrading synthetic reabsorbable fibers (Glycolide, lactide and trimethylene carbonate). These materials

are gradually reabsorbed by the body in a predictable fashion. Preclinical in vivo and in vitro studies have shown favorable results with these materials, and further clinical evaluation with these materials is currently underway.⁴⁸ Fast absorbable prostheses such as polyglactin are not durable and almost never result in long-term correction of an abdominal wall defect but are sometimes useful as a temporary substitute when a nonabsorbable prosthesis is contraindicated (i.e., a grossly infected wound).

GROIN HERNIAS

Groin hernias are described as inguinal and femoral, the inguinal hernias being further subdivided into direct and indirect hernias (some authorities refer to these as medial and lateral hernias, respectively). Groin hernias may be primary or recurrent. An indirect hernia occurs as a protrusion of abdominal contents through the internal ring, lateral to the inferior epigastric vessels, into the inguinal canal. Indirect inguinal hernias (lateral hernias) are situated within the spermatic cord and therefore may extend into the scrotum. In female patients, the hernia follows the round ligament and may present as a swelling in the labium. A direct hernia (medial hernia) is a protrusion through the triangle of Hesselbach medial to the inferior epigastric vessels. These hernias develop through an area where the endoabdominal fascia is not protected by overlying muscle. Direct hernias do not usually involve the cord, as they tend to protrude forward. However, they occasionally track alongside the cord down the entire length of the inguinal canal and even enter the scrotum. For this reason, the only absolute distinction between a direct and an indirect hernia is the relationship to the inferior epigastric vessels. Inguinal hernias are more common in men (with a 15% lifetime risk among men aged > 25 years) with a male to female age-adjusted ratio of 7.5:1.⁴⁹ A femoral hernia protrudes through the femoral canal, which is bordered by the inguinal ligament superiorly, the pubic ramus medially and inferiorly, and the femoral vein laterally. This hernia presents below the inguinal ligament (Fig. 72-21). In a sliding hernia, part of the sac is formed by the viscera, on the left side the sigmoid colon or bladder, and on the right side the cecum or bladder (Fig. 72-22).

Figure 72-21. **A:** Inguinal hernia. This presents above the inguinal ligament and extends below it. **B:** Femoral hernia. This presents below the inguinal ligament.

Epidemiology

1. Inguinal hernias occur in persons of all ages, from the neonate to the elderly. Inguinal hernias constitute approximately 75% of abdominal wall hernias, with femoral hernia accounting for 5%. Femoral hernias are more common in women, but a woman with a groin hernia is still five times more likely to have an inguinal hernia (usually indirect) than a femoral. Incisional, umbilical, and epigastric hernias account for 15% and miscellaneous hernias make up the other 5%. The lifetime risk of developing a groin hernia is approximately 25% in males and 5% in females. Inguinal hernias are more common on the right than the left and are 10 times more likely in males than in females.⁵⁰ Indirect inguinal hernias are twice as common as direct hernias. The reported prevalence of inguinal hernia in the general population varies widely in the literature primarily due to a lack of a consistent reporting mechanism; for example, questionnaire versus actual physical examination. The most reliable data use hernia repair as a surrogate for the prevalence.⁵¹ For example, in a study using the Danish Hospital registry, the country's population of 5,639,885 people was studied. There were 46,717 groin hernia repairs reported between 2005 and 2010 making it possible to estimate prevalence for various age groups as shown in (Fig. 72-23).

Figure 72-22. Sliding hernia (right indirect inguinal).

2. The figure confirms a bimodal incidence pattern peaking at the extremes of life with an initial peak at 0 to 5 years followed by a second peak at 70 to 80 years.⁵¹ Right-sided inguinal hernias are more common than left. In men, indirect inguinal hernias outnumber direct by about 2:1, with femoral hernias making up a much smaller proportion. The literature dealing with groin hernia in women is insufficient making management decisions difficult. For females, indirect inguinal hernias are the most common which are five times more common than femoral hernias, with direct hernias occurring rarely. Overall, femoral hernias account for fewer than 10% of all groin hernias and the prevalence is higher in females than in males. Femoral hernias are especially dangerous as 40% of all femoral hernias present as emergencies, with incarceration or strangulation and need emergency repair which is associated with high mortality. A study from the Swedish Hernia Registry analyzing 90,648 inguinal hernia operations (83,753 males, 6,895 females) between 1992 and 2003 revealed a higher percentage of emergency operations in women (16.9%) than in men (5%).⁵² Femoral recurrences are particularly common in women in whom the diagnosis at the time of the primary repair was a direct inguinal hernia, strongly suggesting a missed femoral hernia at the original procedure since direct hernias are very rare in women. Femoral hernias are also more common in older patients and in those who have previously undergone inguinal hernia repair. Risk factors for the development of an inguinal hernia are listed in [Table 72-3](#).

Classification

The primary purpose of a classification system for any disease is to stratify for severity so that reasonable comparisons can be made between various treatment strategies.⁵³ However, with the multiplicity of operative techniques and approaches for repair of groin hernias, no one classification system has been accepted by all practitioners. The reason why it is so difficult to develop a classification system that all surgeons can agree on is that in the final analysis, the physical examination represents an important component and no one has been able to eliminate its subjectivity. The European Hernia Society, Nyhus, Gilbert, Schumpelick, Harkins, Casten, Halverson and McVay, Lichtenstein, Bendavid, Stoppa, Alexandre, and Zollinger have developed groin hernia classification systems. The European Hernia Society classification is a simple system using three variables, location (M = medial, L = lateral, and F = femoral) and size of the defect (1 [≤ 1 finger], 2 [1 to 2 fingers], and 3 [≥ 3 fingers]) and status (P = primary, R = recurrent, and X = unknown) ([Table 72-4](#)).⁵⁴ This system and the Nyhus system, which is detailed in [Table 72-5](#), are widely used by hernia surgeons.

Table 72-3 Risk Factors for the Development of an Inguinal Hernia

- Male sex
- Increased age
- COPD
- Smoking
- Low body mass index
- High intra-abdominal pressure
- Collagen vascular disease

- History of thoracic aortic aneurysm
- Patent processus vaginalis
- History of an open appendectomy
- Peritoneal dialysis
- Family history

Figure 72-23. Prevalence of combined inguinal and femoral hernia repair (i.e., all groin hernias), stratified by age and gender. The results indicate the percentage of persons at a given age in the population who were operated for a groin hernia during the study period. Example: 4.19% CI 4.04% to 4.34% of all males aged 75 to 80 years in Denmark were operated for a groin hernia at least once during the study period. From Burcharth J, Pedersen M, Bisgaard T, et al. Nationwide prevalence of groin hernia repair. *PLoS One* 2013;8(1):e54367, with permission.

Clinical Diagnosis

Groin hernias present with a swelling that has a cough impulse. With indirect hernias, the swelling may extend down into the scrotum. The swelling reduces when the patient lies down. Sometimes, the hernia does not reduce easily and the patient has to reduce it manually. Applying pressure over the midinguinal point (midway between the anterior superior iliac spine and the pubic tubercle and just above the inguinal ligament) with the fingertip will control an indirect hernia and prevent it from protruding when the patient strains. A direct hernia will not be controlled with this maneuver. Similarly, if the scrotum is invaginated with the index finger and the tip of the finger is placed through the external inguinal ring into the canal, and the patient is then asked to strain, an indirect hernia will push against the fingertip, whereas a direct hernia will push against the pulp of the finger. It should be noted that the accuracy of this clinical assessment is questioned by many authorities. A femoral hernia presents as a swelling below the inguinal ligament and just lateral to the pubic tubercle (Fig. 72-21).

Table 72-4 EHS Classification of Groin Hernias

EHS Groin Hernia		Primary (P)		Recurrent (R)	
	0	1	2	3	x
Lateral (L)					
Medial (M)					
Femoral (F)					

CLASSIFICATION

Table 72-5 Nyhus Classification of Groin Hernias

Type	Description
I	Indirect hernia Normal-sized internal ring Typically in infants, children, small adults
II	Indirect hernia Dilated internal ring Posterior wall intact Inferior epigastric vessels not displaced Does not extend to the scrotum
III	Posterior wall defect
IIIA	Direct hernia Size not taken into account
IIIB	Indirect hernia Dilated internal ring encroaching on Hesselbach triangle (massive scrotal, sliding, or pantaloon type)
IIIC	Femoral hernia
IV	Recurrent hernia
IVA	Direct
IVB	Indirect
IVC	Femoral
IVD	Combined

DIAGNOSIS

Table 72-6 Differential Diagnosis of a Groin Hernia

Hydrocele
Encysted hydrocele of the cord
Varicocele
Epididymo-orchitis
Torsion of the testis
Undescended testis
Ectopic testis
Testicular tumor
Pseudohernia
Femoral artery aneurysm
Saphena varix
Lipoma of spermatic cord
Inguinal lymphadenopathy
Psoas abscess
Cutaneous lesions (e.g., sebaceous cyst and skin tumor)

Differential Diagnosis

The clinical presentation of a groin hernia, especially when large, is frequently obvious to the examiner. Smaller hernias and recurrent hernias can be confused with a number of different conditions that can be mistaken for a hernia (Table 72-6).

A hydrocele extending into the scrotum or an encysted hydrocele of the cord can involve the groin

area. The distinguishing features are that the examining hand can get above a hydrocele but not above a hernia and that a hydrocele transilluminates very clearly. A varicocele does not transilluminate, has the characteristic feel of a “bag of worms,” and is more tube-like in conformation. Lesions of the testicle may sometimes mimic a hernia, particularly in inflammatory conditions, such as epididymo-orchitis. The distinguishing features are intense pain extending down into the scrotum. The testicle itself is enlarged and tender, as is the epididymis. On rectal examination, the seminal vesicles are tender. This condition may be bilateral. Torsion of the testicle is distinguished by the fact that the testicle is absent from the scrotum and the swelling in the groin feels firm. A sonogram reveals a solid mass in the testicle, which has been pulled up because of the torsion. Testicular tumors, if large enough, may extend up to the groin area, but they have a solid feel and sonography can distinguish them.

Pseudohernia is a condition that occurs in patients with denervation of the abdominal wall musculature (e.g., after polio). The abdominal wall muscles bulge forward on straining and have the appearance of a hernia. An aneurysm of the femoral artery may present as a groin swelling but with an expansile impulse and sometimes a bruit. If thrombosis develops in the aneurysm, pulsation may be lost. In this instance, the aneurysm becomes tender. Femoral aneurysms move from side to side but not up and down. A saphena varix usually presents below the inguinal ligament and represents a varicosity of one of the branches of the long saphenous vein as it emerges from the hiatus. It is particularly common in pregnancy. Like a hernia, the varix has a cough impulse and becomes more prominent when the patient is standing. Compression over the femoral hiatus obliterates this lesion. The varix is sometimes associated with varicose veins farther down the lower limb. The overlying skin has an associated bluish discoloration. A lipoma within the spermatic cord is a very common condition and, from anatomic studies and surgical dissection, is now regarded as a hernia of the extraperitoneal fat.⁵⁵ If found at surgery, the lipoma is removed to avoid a persistent bulge in the inguinal region despite a successful hernia repair.

Enlargement of inguinal lymph nodes may also be mistaken for herniation. Inflammatory nodes are usually tender; metastatic lymphadenopathy is usually not tender. If inguinal lymph nodes are replaced by metastasis, a primary lesion should be looked for in the skin in any part of the lower limb. The perineum and anal canal should also be examined. Lymphadenopathy can also be caused by lymphoma, and groin nodes may be the only site. Lymphadenopathy characteristically appears as a well-circumscribed mass below the inguinal ligament that one can get above with the examining hand. Lymph nodes are solid on ultrasonography, and for this reason, it may be difficult to differentiate nodes from a femoral hernia containing omentum.

Surgical Indications

5 Historically, surgeons have recommended repair of inguinal hernias at diagnosis unless specific contraindications are present. This recommendation is based on the presumption that the morbidity and mortality associated with a bowel obstruction and/or strangulation is greater than the risks of operation. This concept was challenged for asymptomatic or minimally symptomatic patients based on two randomized controlled trials comparing a strategy of watchful waiting to routine repair for male inguinal hernia patients with minimal symptoms. In 2006, Fitzgibbons and colleagues randomized 724 patients to watchful waiting versus tension-free hernia repair from five North American Centers and found no difference in quality of life at 2 years and an acceptably low rate of hernia accidents (1.8 per 1,000 patient-years) in the watchful waiting group.⁵⁶ Similar results were determined in the other trial conducted in the United Kingdom.⁵⁷ It should be noted that long-term follow-up from these randomized controlled trials have demonstrated a crossover rate of up to 70% by 10 years for patients in the watchful waiting group, with crossover being much higher for patients older than 65 years of age.⁵⁸ The most common reason for crossover was increasing pain. Despite the high crossover rate, only 2.5% of the patients in the watchful waiting group developed incarceration for which they underwent surgery with no mortality. In summary, watchful waiting is a safe strategy for asymptomatic or minimally symptomatic hernias. However, patients who opt for this strategy should be informed that it is safe to delay surgery for several years, but increasing symptoms will more than likely make them choose to have their hernia repaired over the next 10 years.

An alternative to surgical repair is a mechanical device known as a truss which consists of a belt with a pad that is applied to the groin after spontaneous or manual reduction of a hernia and has been used for centuries. It serves to maintain reduction and possibly prevents enlargement of the hernia. There are insufficient studies to determine how effective trusses actually are and whether they are as good as surgery for the control of symptoms. Most patients find them cumbersome to use and difficult to keep

clean. With prolonged usage, atrophy of the spermatic cord has been reported and eventual surgical repair is made more difficult due to fibrosis of the tissues. However, some patients do achieve symptomatic relief.

Algorithm 72-1. Management of initial inguinal hernia.

Preoperative Considerations

Most elective groin hernias can be repaired on outpatient basis. Local anesthesia is sufficient for most cases of open inguinal hernia repairs with or without supplemental intravenous sedation. Its greatest advantage is the virtual elimination of urinary retention when compared to regional or general anesthesia.⁵⁹ General anesthesia is an acceptable alternative and is preferred by many surgeons. Indeed, epidemiologic information from databases primarily in Europe disclose that local anesthesia is used in only about 10%.⁶⁰ Regional anesthesia has the highest incidence of cardiovascular complications and should be avoided.⁶¹ Laparoscopic hernia repairs require general anesthesia and can only be performed in patients who can safely tolerate general anesthesia and a pneumoperitoneum. Antibiotic prophylaxis has not been shown to be of any value except in patients at high risk for infection.⁶² Nevertheless, it is routinely used in the United States because of medicolegal considerations when placing prosthesis.

Surgical Treatment of Groin Hernias

6 Four developments in the latter half of the 20th century significantly decreased morbidity and favorably influenced the recurrence rate to the currently accepted level of less than 2%: (a) the routine use of prosthetic materials, (b) the widespread acceptance of the “tension-free” concept, (c) the realization that the preperitoneal space can be used for hernia repair, and (d) therapeutic laparoscopy (Algorithms 72-1 and 72-2). These concepts are discussed in this section; the treatment strategies are divided between an open approach in the conventional anterior space and a preperitoneal approach, either open or laparoscopic.

Open Approach

The simplest Nyhus type I indirect inguinal hernias, which include most inguinal hernias in children, are adequately treated by obliteration of the congenital patent processus vaginalis alone. Since the inguinal floor is otherwise normal, reconstruction is not required. Classically, the hernia sac is dissected from the cord structures, ligated, and removed at its origin at the internal ring, the so-called high ligation of the sac, thus the term *herniotomy*. The skin incision starts at the pubic tubercle and is extended laterally. The external oblique aponeurosis is opened in the line of its fibers through the external ring and the lower leaf is freed from the spermatic cord. The spermatic cord is freed from the floor of the inguinal canal and the pubic tubercle. Mobilization of the cord structures is completed by means of blunt dissection, and a Penrose drain is placed around them so that they can be retracted during the procedure.

The genital branch of the genitofemoral nerve and the spermatic vessels are included with the cord. The ilioinguinal and iliohypogastric nerves are usually preserved. The cremasteric fibers are separated, and the hernia sac is dissected from the cord structures to a point proximal to the internal ring. Ligation

can be performed at this point (high ligation), followed by division of the neck of the sac. Prior to this, the sac can be opened to allow a digital examination of the abdominal cavity and femoral ring. Alternatively, the sac may be simply inverted. The proponents of not opening the sac feel that with this method the patient experiences less pain because the highly innervated peritoneum has not been violated.

The terms *herniorrhaphy* or *hernioplasty* are used when a procedure to reconstruct the inguinal floor is added. For indirect hernias, the sac is first dealt with in an identical manner as for a herniotomy. The only exception is large indirect inguinal scrotal hernias where complete removal of the sac might result in too high of an incidence of cord and testicular complications because of the extensive dissection required to completely separate them from the cord. Most authorities believe that these large sacs are best transected at the midpoint of the canal, and the distal sac is left in situ. Direct hernia sacs are almost never removed but instead are dissected from surrounding structures and reduced into the preperitoneal space. Dividing the transversalis fascia circumferentially at the neck (base) of the sac will aid in this reduction in some cases. The defect may be closed primarily at this point to maintain the reduction while a formal repair is being performed. The latter is considered a matter of convenience and adds nothing to the strength of the final outcome. The area of weakness in the posterior wall is then reinforced with the patient’s own tissues.

Algorithm 72-2. Management of recurrent inguinal hernia.

The next step is to reconstruct the inguinal floor. There are two ways to do this. The first is a tissue repair, so named because only the patient’s native tissue is used without foreign prosthetic material. The second is the tension-free repair (TFR). This implies the use of a prosthesis to repair the weakened inguinal floor, eliminating the need to reapproximate tissues that were not in apposition naturally. Edoardo Bassini (1844–1924) is considered the father of modern inguinal hernia surgery because in the latter part of the 19th century he introduced the first tissue repair based on solid anatomic principles, which became the “gold standard” for inguinal hernia repair for most of the 20th century. His scientific approach led to the development of several distinct steps essential for the procedure (Table 72-7). Before Bassini’s achievements, elective herniorrhaphy was almost never recommended because the results were so bad.

TREATMENT

Table 72-7 Essential Steps for the Inguinal Hernia Repair

1. Complete division of the external oblique aponeurosis and the transversalis fascia
2. Differentiation between indirect and direct defects
3. Isolation of the spermatic cord
4. Ligation and removal of the sac at the deep inguinal ring flush with the peritoneum
5. Oblique reconstruction of the inguinal canal with an anterior and posterior wall and an internal and external ring

Today, there are at least 70 named tissue repairs described in the literature.⁶³ Most are relatively minor modifications of the Bassini, Shouldice, and McVay repairs and therefore, for the purposes of this chapter, only these will be presented. In the Bassini repair, the transversus abdominis aponeurosis together with the transversalis fascia is sutured to the shelving edge of the inguinal ligament with nonabsorbable interrupted sutures (Fig. 72-24). In the Shouldice repair, the transversalis fascia is divided from the internal ring to the pubic tubercle. The musculofascial elements laterally are then sutured to different levels of the inferior flap of the external oblique aponeurosis with four rows of running sutures (Fig. 72-25). Although the suture material originally used for this repair was stainless steel wire, other nonabsorbable materials, such as Prolene, are now used. The McVay repair (Fig. 72-26) addresses both inguinal and femoral hernias. The central attenuated portion of the inguinal floor is excised. The Cooper ligament must be clearly identified. The inguinal floor is then repaired by approximating the transversus abdominis aponeurosis and transversalis fascia to the Cooper ligament between the pubic tubercle and the femoral vein. A so-called transition stitch is then necessary between the transversalis fascia, Cooper ligament, and inguinal ligament to bring the repair above the femoral vessels. The repair is then continued laterally along the inguinal ligament.

A relaxing incision is necessary for repairs of large indirect hernias and whenever the McVay repair is used. Failure to make a relaxing incision has been implicated in a greater incidence of recurrence. The relaxing incision is made in the anterior rectus sheath in a vertical direction and is extended 3 to 4 cm above the pubis to a level opposite the internal ring (Fig. 72-26). The resulting defect in the sheath is protected posteriorly by the body of the rectus muscle, which prevents herniation at that site.

Figure 72-24. Bassini repair.

Figure 72-25. Shouldice repair.

Figure 72-26. McVay (Cooper ligament) repair.

As population-based studies began to supplant personal series, it became obvious that the recurrence rate for tissue repairs with the exception of the Shouldice repair approached 10% to 15% in the general surgical practice.⁶⁴ In the 1990s, widespread adoption of the routine use of prosthesis (usually a mesh material) as popularized by Lichtenstein has resulted in the near elimination of the Bassini approach in the United States with recurrence rates decreasing by 50% to 75%.⁶⁵ The Lichtenstein operation or open mesh herniorrhaphy, which is considered the “gold standard” operation for inguinal hernias with a recurrence rate of 1% to 1.6% (Fig. 72-27).⁶⁶ The initial dissection is identical to the tissue repairs described. Once the sac has been dealt with, a 15 × 11-cm sheet of polypropylene mesh is used, the medial end of which is rounded to the shape of the medial corner of the inguinal canal. This medial end is sutured to the anterior rectus sheath 2 cm medial to the pubic tubercle. In deference to nerve entrapment, most surgeons now use an absorbable suture, something considered heresy in the past. The same suture is then continued laterally in a running locking fashion securing the inferior edge of the prosthesis to either side of the pubic tubercle and the shelving edge of the inguinal ligament. The periosteum of the bone is avoided to prevent osteitis pubis. The suture is continued to attach the lower edge of the prosthesis to the shelving edge of the inguinal ligament up to a point just lateral to the internal ring. If a femoral hernia is present, the posterior surface of the mesh is sutured to the Cooper ligament after the inferior edge has been attached to the inguinal ligament. Alternatively, the inferior edge of the prosthesis is sewn directly to Cooper ligament medially and then transitioned to the inguinal

ligament over the femoral vessels. Both techniques close the femoral canal. A slit is cut in the lateral end of the mesh to produce a narrow (one-third width) tail below and a wider (two-thirds width) tail above. The spermatic cord is positioned between the two tails. The wider tail is placed over the narrow one and a so-called shutter valve stitch placed just lateral to the cord including the inferior surface of the superior tail, the inferior surface of the inferior tail, and the inguinal ligament. The tails are then tucked under the external oblique aponeurosis to the level of the anterior superior iliac spine. The external oblique aponeurosis is closed to re-create the external ring. The wound is closed in layers.

Figure 72-27. The Lichtenstein hernioplasty, showing placement of the mesh.

A popular modification of the Lichtenstein operation has been termed the plug-and-patch repair. As the name implies, a plug usually constructed from polypropylene is inserted in the defect and secured with interrupted sutures to either the internal ring (for an indirect hernia) or the neck of the defect (for a direct hernia). The patch is then placed over the plug to cover the inguinal floor as in the Lichtenstein. One might argue that this operation is nothing more than a Lichtenstein on top of a plug, and in fact the term “plugstenstein” has been used to describe it. However, the difference with a plug-and-patch repair is that only one or two sutures – or, sometimes, no sutures – are used to secure the flat prosthesis to the underlying inguinal floor. This results in an operation that is fast and very easy to teach. However, based on trials comparing the plug and patch to the Lichtenstein technique, no benefit with respect to recurrence rate and/or chronic pain has been demonstrated.⁶²

Preperitoneal Approach

The preperitoneal space is situated between the transversalis fascia and the peritoneum. The final common denominator in all groin hernias is failure of the transversalis fascia to retain the intra-abdominal contents. Repairs performed in this space make the distinction between direct, indirect, and femoral irrelevant because the repair is accomplished behind the defective transversalis fascia, addressing the entire myopectineal orifice.

For a conventional, open operation, the preperitoneal space can be entered via a lower midline incision or a transverse incision placed slightly higher than usual. The rectus muscle is retracted medially and the preperitoneal space entered. A large prosthesis is used that extends far beyond the margins of the myopectineal orifice and envelops the visceral sac. The mesh is held in place by intra-abdominal pressure, which pushes outward toward the undersurface of the transversalis fascia. If the hernial sac is large, it is amputated or inverted beneath a purse-string suture to smooth the external surface of the visceral sac. The distal peritoneal sac is left in place, undissected, and attached to the cord. With a sliding indirect hernia, the sac is easily dissected away from the cord. Proponents of this technique feel that polyester is better suited than other prostheses because of its pliability. For a bilateral repair, one large chevron-shaped mesh can be used for both sides. One disadvantage of this technique is the need for a larger incision and substantial amount of dissection and the associated pain. Laparoscopic hernia repairs avoid the disadvantages of a large incision while providing the advantages of preperitoneal repair.

Several newer, less invasive preperitoneal techniques have been developed to place a mesh in the preperitoneal space. For example, in the Kugel procedure, a small incision is made over the deep inguinal ring and the preperitoneal space is developed bluntly followed by the use of a prosthesis with

an incorporated reinforcing ring. This ring can be deformed to allow the prosthesis to be introduced into the preperitoneal space and then the ring causes it to spring back to its original shape, providing wide overlap of the myopectineal orifice.⁶⁷ The procedure works well in experienced hands but because it is partially blind, considerable training is required. In addition, in earlier designs, the peripheral memory recoil ring was made of polyethylene terephthalate which had a tendency to fracture over time occasionally resulting in injury to nearby viscera.⁶⁸ Another approach is to take advantage of both the preperitoneal space and the conventional anterior space using a bilayered prosthesis in which a cylinder of prosthetic material connects the two layers through the hernia defect or the internal ring.⁶⁹ One such prosthetic is the Prolene Hernia System (PHS) where both an onlay and sublay mesh is placed. Trials comparing PHS to the Lichtenstein technique have not shown any difference with respect to recurrence rate and chronic pain.⁶² The objection to this system is that both the conventional anterior and the preperitoneal spaces are dissected making the repair of a recurrence more difficult.

Laparoscopic Approach

The terminology to describe a laparoscopic inguinal herniorrhaphy can be confusing. A laparoscopic preperitoneal hernia repair, in which a laparoscopy is performed and the preperitoneal space is entered with a second incision in the peritoneum, is called a *transabdominal preperitoneal repair*, or TAPP repair. An inguinal hernia repair in which prosthetic material is placed intraperitoneally over the defect under laparoscopic guidance is referred to as an *intraperitoneal onlay mesh repair*, or IPOM repair. The third general type of laparoscopic approach is the *totally extraperitoneal laparoscopic repair*, or TEP repair. Laparoscopy, by definition, implies that the peritoneal cavity has been entered. To refer to this technique as *extraperitoneal* therefore represents a contradiction in terms. However, because a laparoscope and related instruments are used, it is fitting to discuss the extraperitoneal approach along with the other laparoscopic inguinal herniorrhaphies.

The TAPP and the TEP laparoscopic inguinal herniorrhaphies are the most popular. Both are modeled after the conventional preperitoneal operations. The major difference is that the preperitoneal space is entered through three trocar sites rather than through a large conventional incision. The ensuing radical dissection of the preperitoneal space with placement of a large prosthesis is similar to the conventional preperitoneal operation.

Laparoscopic Versus Conventional Herniorrhaphy. Randomized controlled trials as well as a meta-analysis of pooled data from these trials have shown that on average, patients undergoing laparoscopic herniorrhaphy have less pain initially than open, tension-free herniorrhaphy and return to normal activities sooner with a lower incidence of wound infection and hematoma and less chronic pain/numbness.^{61,70} The difference is even greater when the comparison is made to nonprosthetic repairs. For recurrent hernias after conventional open repair, laparoscopic inguinal hernia repair results in lesser postoperative pain and faster convalescence. However, the potential advantages of laparoscopic hernia repair must be interpreted in light of the disadvantages, which include significantly longer operative time and complications related to the laparoscopy such as bowel perforation or major vascular injury, potential adhesive complications at sites where the peritoneum has been breached or prosthetic material has been placed, the need for a general anesthetic, and increased cost because of the expensive equipment. On the other hand, the conventional operation can be performed under local anesthesia on an outpatient basis, with minimal risk of intra-abdominal injury, and the cost is less. A long steep learning curve exists for laparoscopic hernia repairs, especially TEP, and an unacceptably high recurrence rate may be seen when this procedure is performed by inexperienced surgeons without appropriate training and mentoring. A recent meta-analysis including 27 randomized trials as well as an additional cohort study revealed a statistically significant higher risk of recurrence of primary hernias after laparoscopic repair as compared with open repair. The clinical significance of this is questioned because the absolute numbers were not impressive, that is, reoperation rates in the cohort study, 4.1% versus 2.1%.^{71,72} The operation is particularly difficult if a previous operation has been done in the preperitoneal space (e.g., the index hernia repair or a prostatectomy) because of scarring with significant risk for bladder or vascular injury. Despite the expected advantages, the choice between laparoscopy and other techniques still depends on local expertise availability. Only dedicated centers are able to routinely offer laparoscopy for a recurrent inguinal hernia.

Patient and Procedure Selection. Assuming equivalence for recurrence and complication rates between laparoscopic and open tension-free hernia repair for a given surgeon, all adult patients with inguinal hernias who are candidates for general anesthesia can be considered candidates for laparoscopic inguinal hernia repair. Certain hernia types, such as those that are recurrent, bilateral, or otherwise

complicated, are particularly suited for the laparoscopic approach.^{73,74} In addition, women may be better served with a laparoscopic operation because the femoral space is addressed, which should eliminate the excessive incidence of femoral recurrence observed with conventional operations such as the Lichtenstein.⁵² Contraindications to laparoscopic inguinal hernia repairs include intra-abdominal infection and coagulopathy. Relative contraindications for laparoscopic inguinal hernia repair include intra-abdominal adhesions from previous surgery, ascites, or previous retropubic space surgery, because of the increased risk for bladder injury. Severe underlying medical illness is also a relative contraindication because of the added risk of general anesthesia and these patients are better suited for a conventional operation under local anesthesia. An incarcerated sliding scrotal hernia is a relative contraindication, especially when it involves the sigmoid colon, because of the high risk for perforation during the dissection.

Operative Techniques

Transabdominal Preperitoneal Repair. The procedure is begun with a thorough diagnostic laparoscopy done through an umbilical cannula to rule out unrelated pathology and carefully inspect both myopectineal orifices. Two additional cannulas are placed just lateral to the rectus sheath on either side of the umbilicus (Fig. 72-28). For a unilateral hernia, a transverse incision is begun at the lateral side of the medial umbilical ligament and extended to open its lateral leaf to the anterior superior iliac spine. If the medial umbilical ligament appears to compromise exposure, it can be divided. Electrocautery is used to minimize bleeding from the remnants of the embryologic umbilical artery. A radical dissection of the preperitoneal space is then performed with mostly blunt dissection and generous use of electrocautery, as bleeding in this area is particularly troublesome if it interferes with illumination. The ipsilateral and contralateral pubic tubercles, inferior epigastric vessels, Cooper ligament, and iliopubic tract are identified (Fig. 72-29). The cord structures are mobilized, and the peritoneal flap is dissected several centimeters proximal to the bifurcation of the vas deferens and the internal spermatic vessels. Recurrences have been attributed to inadequate mobilization of the peritoneal flap, which does not allow the prosthesis to lie flat in this area. If small, an indirect sac is mobilized away from the cord structures and reduced. If large, the sac is divided at a convenient point distal to the internal ring and only the proximal portion is mobilized. A direct sac readily reduces during the preperitoneal dissection. An easily visible layer of fatty tissue separates the thinned out transversalis fascia lining the defect and the peritoneum.

A large piece of polypropylene mesh (at least 14 × 11 cm) is placed in the preperitoneal space to cover the contralateral pubic tubercle medially and extending onto the anterior abdominal wall superiorly at least 2 cm above the hernia defect, to the anterior superior iliac spine laterally, and over the Cooper ligament inferiorly. Most surgeons prefer to fasten the prosthesis with staples, tacks, or glue, but there is increasing evidence that fixation is not necessary when a large prosthesis is used that widely overlaps the entire myopectineal orifice. Staples or tacks are never placed below the iliopubic tract when lateral to the internal spermatic vessel because of the danger of damage to the important nerves in this area. The last step is to cover the prosthesis by closing the peritoneum with sutures, tacks, staples, or glue.⁷⁵ The goal is to isolate the prosthesis from the abdominal viscera rather than to always achieve precise approximation of the peritoneal edges. This is because gaps can form if the peritoneum is closed under tension allowing bowel to migrate into the preperitoneal space. A better option is to secure the inferior peritoneal flap to the transversalis fascia above the prosthesis and leave the superior flap alone.

For bilateral inguinal hernias, the same peritoneal incision and preperitoneal dissections are used. The symphysis pubis is completely exposed so that both preperitoneal dissections communicate with each other. This exposure allows the placement of one large prosthesis (at least 25 × 8 cm) that essentially covers the entire lower pelvis. By not incising the peritoneum between the two medial umbilical ligaments, one avoids the theoretical complication of dividing a patent urachus.

Totally Extraperitoneal Repair. An incision is made at the umbilicus, as if one were planning to perform open laparoscopy. The rectus sheath is opened on one side and the rectus muscle is retracted laterally. Blunt dissection is then begun in the space between the rectus muscle and the posterior rectus sheath. Once the space is large enough, two additional cannulas are placed in the midline, one approximately 5 cm above the symphysis pubis and the other midway between the umbilicus and the symphysis pubis. The dissection of the preperitoneal space is completed under direct vision. The rest of the operation is identical to the TAPP procedure described previously except that peritoneal closure is not necessary. Popular alternatives are to use a water- or air-filled balloon dissector to perform the

preperitoneal dissection and to place the two accessory cannulas on either side of the umbilicus, as in the TAPP procedure, instead of in the midline.

Figure 72-28. Typical operative setup and cannula site selection for a transabdominal preperitoneal (TAPP) laparoscopic inguinal herniorrhaphy.

Figure 72-29. Important structures that must be identified after a preperitoneal dissection: inferior epigastric vessels, Cooper ligament, spermatic vessels, vas deferens, iliopubic tract, genitofemoral nerve, femoral nerve, lateral femoral cutaneous nerve, ilioinguinal nerve, iliacus muscle, and psoas major muscle.

The presumed advantages of the TEP procedure are that the inherent complications of entering the peritoneal cavity, such as intra-abdominal organ injury or postoperative bowel obstruction secondary to adhesions or trocar site herniation, are avoided. However, the operative space is limited, and considerable experience is required to become familiar with the anatomy from this perspective. In addition, it is not yet clear whether inadvertent breaches in the peritoneal cavity that are difficult to

visualize because of the direction of the optics might negate the potential benefits of this approach.

Intraperitoneal Onlay Mesh Repair. The TAPP and the TEP herniorrhaphies are better considered minimal access procedures rather than minimally invasive because of the extensive dissection required in the preperitoneal space. The IPOM procedure was developed to be a truly minimally invasive operation. By placing the prosthesis one layer deep to the preperitoneal space directly onto the peritoneum, one can eliminate the need for a radical preperitoneal dissection. Initial laparoscopy and accessory cannula placement are the same as in the TAPP procedure. A large piece of prosthetic material is introduced into the peritoneal cavity and secured in place with staples, tacks, or sutures. An attempt is made to use the same landmarks described previously for the TAPP procedure. The main concern is development of the complications of intraperitoneal placement of a prosthesis in contact with intra-abdominal organs. The procedure is regaining some popularity because of the development of the adhesion barrier prosthetics for ventral hernia repair.

Special Considerations: Pediatric Hernias

Given the high incidence of indirect inguinal hernias due to a patent processus vaginalis in pediatric patients, hernia repairs are completed using a high ligation technique. Concerns exist with the use of mesh in adolescents with respect to effect on fertility, long-term groin pain, and infection risk.^{76,77} Postpubertal males have a similar anatomy to the adult population with a larger inguinal ring diameter and variations on transverse fascia defects. It is unclear as to which age/size does a child become an adult with respect to principles of hernia repair. Longitudinal studies comparing different hernia repair techniques in adolescents are needed before we can determine optimal treatment for adolescents especially those with weak inguinal floors and direct hernias.

Femoral Hernias

Femoral hernias are much rarer and account for 2% to 4% of groin hernia repairs and can present a challenge to even the most experienced surgeon. As such, femoral hernias are more common in women and often present with an acute episode of incarceration, intestinal obstruction, or strangulation, so that emergency surgery is necessary. It can be difficult to reduce the hernia at surgery, and it is not uncommon to have to divide the inguinal ligament to obtain greater freedom to perform this reduction. Femoral hernias can be repaired from a lower approach, in which a vertical incision is made over the femoral triangle in the upper thigh. The hernia is approached from below the inguinal ligament and reduced, and then the defect is closed by suturing the inguinal ligament to the Cooper ligament from below. An alternative is to insert a rolled plug of mesh into the defect and suture the periphery to the inguinal ligament and Cooper ligament.⁶⁶ The repair can also be carried out from above via an inguinal approach, as in the McVay repair. The posterior floor of the inguinal canal is dissected out, and the Cooper ligament is repaired after the hernia has been reduced. A third type of femoral hernia repair is the preperitoneal repair. Access to the preperitoneal space is gained through an abdominal incision or laparoscopy. A recent study based on the Swedish national register revealed that preperitoneal mesh techniques (both laparoscopic and open) are a better choice for women with femoral hernias.⁷⁸ As effective as the Lichtenstein operation is for men, it may not be the best choice for woman. This is because the Lichtenstein operation, unless modified, only addresses an inguinal hernia and not a femoral hernia. On the other hand, the preperitoneal herniorrhaphies result in coverage of the entire myopectineal orifice and thus both femoral and inguinal hernias are treated. Indeed, in the Swedish study a much higher femoral recurrence rate was observed in women compared to men especially after the repair of a direct inguinal hernia. This is significant because direct hernias are almost unheard of in women providing strong evidence that the femoral hernia was actually missed at the index operation.⁵²

SPORTS HERNIA/ATHLETIC PUBALGIA

The term *sports hernia* is confusing because, by definition, these patients do not actually have a hernia but rather a weakness of the posterior inguinal floor. This condition has received considerable attention in the lay press because of its prevalence in high-profile athletes involved in sports who require rapid changes in direction of the hip area such as soccer, football, basketball, track and field, tennis, and hockey. Alteration in the complex balance that must be maintained between the lower abdominal muscles and the leg adductor muscles and tendons, all revolving around the area of the pubic bone, is the final common denominator for many of the conditions that cause groin pain in up to 5% of athletes

(Fig. 72-30).⁷⁹ The first step in approaching these patients is to make sure that one is not dealing with a cause outside of the groin with referred pain, such as lumbosacral radiculopathic pain, prostatitis, hip disease, and a gastrointestinal cause. The differential diagnosis is listed in Table 72-8.

Figure 72-30. Complicated arrangement of muscle pulling in different directions that attach to the pubic bone.

DIAGNOSIS

Table 72-8 Conditions Other Than a Hernia Associated With Groin Pain

- Nerve entrapment
- Adductor tenoperiostitis
- Pelvic stress fractures
- Osteitis pubis
- Symphysis syndrome
- Gilmore groin (groin disruption)
- Iliopsoas bursitis
- Tendinopathies
- Posterior inguinal wall insufficiency or avulsion fractures
- Synovitis
- Osteoarthritis
- Legg–Calvé–Perthes disease
- Slipped femoral capital epiphysis
- Osteochondritis dissecans or avascular necrosis of the femoral head
- Acetabular labral tears
- Prostatitis
- Epididymitis
- Nephrolithiasis
- Urinary tract infection
- Lymphadenitis

Some authorities prefer to refer to this condition as “athletic pubalgia,” as this conveys the concept that the physical examination is inconclusive and the cause of groin pain is unclear. Imaging may be performed by ultrasound, but cross-sectional imaging (CT or magnetic resonance imaging [MRI]) is the most useful diagnostic modality in the absence of a highly experienced ultrasonographer.⁸⁰ Compared to CT, MRI provides excellent overall anatomic detail especially with the development of fast imaging scanners that will allow dynamic imaging (i.e., performed during straining) with or without the addition of intraperitoneal contrast agents.

The initial treatment is conservative with forced inactivity, elastic immobilization bandages, ice/massage, nonsteroidal anti-inflammatory analgesics, and occasional steroids (systemic and/or local). Surgery is a last resort. Although lacking clear-cut anatomic justification, a mesh hernia repair similar to either an anterior Lichtenstein or a TEP laparoscopic operation is the most popular procedure, sometimes combined with a variety of muscle reattachment procedures and tenotomies. The best results are obtained with a multidisciplinary approach including a surgeon, an orthopedist, a physical therapist, and a sports medicine physician. Not surprisingly, the results are variable given the lack of objective criteria to recommend operation but can be gratifying in some in this motivated group of patients.

Complications of Inguinal Hernia Repair

Complications Related to the Patient

Urinary Retention. The most common predisposing factor for urinary retention after a hernia repair is the use of general or regional anesthesia.⁵⁹ Meta-analyses of randomized controlled trials comparing various hernia techniques performed under general anesthesia have not shown a difference in urinary retention rates.^{81–84} Predisposing factors for urinary retention include overhydration with intravenous fluid during surgery, use of opioid analgesics, older age, prostatic symptoms, and prolonged operative time.^{85,86} Intermittent catheterization or temporary placement of an indwelling urinary catheter is usually adequate therapy. Prophylactic and therapeutic use of alpha adrenergic blockers including prazosin and tamsulosin have been shown in some studies as an effective strategy to prevent postoperative urinary retention.^{87,88}

Ileus. Ileus can be seen with either the conventional or the laparoscopic procedure but is more common with the latter. Treatment is symptomatic, and spontaneous resolution is the rule. Nasogastric decompression is occasionally needed.

Complications Related to the Herniorrhaphy

Recurrence. A lower risk for recurrence with the use of prosthetic material for the repair of an inguinal hernia has been clearly proven by meta-analysis.⁸⁹ Recurrence rates of 2% or less are now routinely reported from specialty centers performing either laparoscopic or conventional TFRs. Although the recurrence rate for hernia repairs is less than 1% at the Shouldice Clinic, others have not been able to duplicate this outstanding record with this or any of the other nonprosthetic repairs.⁹⁰ Complications during the first month after surgery; operation for recurrence; and sutured repairs without mesh, with either anterior or preperitoneal techniques, are associated with an increased recurrence rate. A laparoscopic approach is also considered a risk for recurrence because of its higher potential for technical failure, especially in the less experienced. This was felt to be the most likely reason for a higher recurrence rate at 2 years in a Veterans Affairs study for the laparoscopic approach (10%) compared to an open TFR (4% for the Lichtenstein repair).⁹¹

A consistent definition of a recurrent hernia does not exist because of the difficulty in differentiating a lipoma of the cord, a seroma, or an expansile bulge of the internal oblique muscle from a true hernia recurrence. It may be that reoperation rates as a surrogate provides the most accurate data.⁹² From a clinical standpoint, a hernia should not be classified recurrent unless there is a visible bulge or there is unequivocal evidence of a hernia by an imaging modality such as ultrasound, CT, or MRI. This is especially important for patients who present with pain after their hernia repair because their pain is likely due to a preoperative condition other than the hernia or a postinguinal herniorrhaphy pain syndrome which might be exacerbated by further groin surgery. Femoral recurrences are seen after a Lichtenstein repair because the femoral canal is not routinely closed with the classic technique.⁵²

The general principle for managing recurrent hernias depends on the original repair. The logical approach is to perform the herniorrhaphy in the space that has not been dissected. If the patient had a previous conventional repair, then a preperitoneal repair is best chosen. On the other hand, if the index operation was a preperitoneal one, then a repair that is performed in the conventional inguinal space is best. The dissection of the preperitoneal space after a failed herniorrhaphy has been performed is particularly challenging, with significant risk for vascular, neurologic, and bladder injury.

7 Postherniorrhaphy Groin Pain. Now that the recurrence rate has been brought down to a minimum using modern hernioplasty techniques, chronic postoperative groin pain syndromes (persisting > 3 to 6 months post surgery) have emerged as the biggest issue facing inguinal hernia surgeons ([Algorithm 72-3](#)). Poobalan and colleagues published a critical review of inguinal herniorrhaphy studies between 1987 and 2000.⁹³ The frequency of at least some long-term groin pain was as high as 53% at 1 year (range,

0% to 53%). On average, moderate or severe postherniorrhaphy groin pain probably occurs in about 10% of patients. Several factors have been suggested to be related to the development and intensity of postherniorrhaphy including psychological status, presence of preoperative pain at surgical site, nerve injury, intraoperative nerve handling, surgical technique (open vs. laparoscopic), and acute postoperative pain. Risk prediction model for persistent postoperative pain–based preoperative, intraoperative, and postoperative factors can be helpful in predicting which patients will be more likely to suffer from postherniorrhaphy pain.⁷⁶

Algorithm 72-3. Management of groin pain after herniorrhaphy.

Perhaps the most important single determination for the chronic postherniorrhaphy pain patient is to decide whether the pain is the same or different from that which brought the hernia to the attention of the physician in the first place. There are a variety of conditions that cause groin pain (Table 72-8). CT, ultrasonography, herniography, laparoscopy, and MRI all have their place in the evaluation of these patients. MRI is perhaps the most beneficial because of its ability to differentiate between muscle tear, osteitis pubis, bursitis, and stress fracture. Strain of the adductor muscle complex (adductor longus, brevis, magnus, and gracilis muscles) is commonly overlooked in this group.

True postherniorrhaphy groin pain should be divided into two types: (a) nociceptive pain, which is caused by tissue damage, is further subdivided into somatic and visceral pain, and (b) neuropathic pain due to direct nerve damage. Somatic pain is the most common and is usually caused by damage to ligaments, tendons, and muscles. Visceral pain refers to that which is related to a specific visceral function such as urination or ejaculation (see dysejaculation syndrome, later). Neuropathic pain is much less common but is important to recognize because surgical treatment is possible if the cause is incorporation of a nerve in staples or suture material. The nerves that are usually involved are the ilioinguinal nerve, the iliohypogastric nerve, both the genital and femoral branches of the genitofemoral nerve, and the lateral cutaneous nerve of the thigh. The former two are especially prone to injury during a conventional herniorrhaphy, whereas the latter are most likely damaged during laparoscopy. A femoral nerve injury is extremely rare and is usually the result of a gross technical misadventure. Pain and/or paraesthesia in their distribution characterize patients' symptoms for the more common nerves. There is significant overlap of these nerves, and therefore, it is commonly difficult to sort out exactly which nerve is damaged. Both nociceptive and neuropathic pain is best treated initially with reassurance and conservative treatment with anti-inflammatory medications and local nerve blocks because these will frequently resolve spontaneously. An exception is the patient who complains of severe pain

immediately (i.e., in the recovery room). This patient may be best served by immediate re-exploration before scar tissue develops. When groin exploration is required, triple neurectomy and neuroma excision, adhesiolysis, and foreign body removal (i.e., mesh or suture) are options for treatment. The patients reoperated for persistent pain after hernia surgery often experience a reduction in pain, but a small percentage of patients experience no relief or even worsening of their symptoms.⁹⁴ Given the heterogeneity of the problem, further well designed studies are necessary to identify patient population that may benefit the most from surgical intervention.

Cord and Testicles

Infertility. Infertility caused by inguinal hernia surgery is a recognized complication. The cause of infertility can be related to either the vas deferens or the testicle. The incidence of injury to the vas deferens during inguinal herniorrhaphy has been estimated at 0.3% for adults and between 0.8% and 2% for children.⁹⁵ Injury to the testicle, which eventually leads to atrophy, is estimated to occur in about 0.5% for primary hernia repairs but increases 10-fold to 5% for recurrent repairs. Injuries to the vas deferens that may present as an obstruction include division, ligation, clipping, stapling, electrocauterization, devascularization, and scarification. In addition, there is evidence that there is a small subset of patients whose inflammatory response to mesh is so severe that vasal obstruction results.⁹⁶ In addition to obstruction, traction injuries during normal cord mobilization may damage the muscular layer of the vas deferens, which then interferes with rapid sperm transfer during ejaculation.⁹⁷ Sperm antibodies may develop as a result of extravasation of sperm at an injury site, which is why a unilateral injury can also result in infertility. The role of mesh in the causation of infertility has been implicated by some small case series and case reports. Ironically, one of the major arguments for the routine use of mesh in inguinal hernia surgery is to preserve fertility. The theory is that by decreasing the generally accepted recurrence rate in the general population from 10% to 15% seen with Bassini and its variants to less than 5% with the mesh tension-free approach, reoperative surgery, with its heavy toll of testicular loss, is avoided.⁹⁸

Ischemic Orchitis. Damage to the blood supply of the testicle can cause ischemic orchitis and testicular atrophy.⁹⁷ Ischemic orchitis occurs in about 1% of primary hernioplasties but is much more common with operations performed for recurrent hernias.⁹⁹ It manifests as postoperative inflammation of the testicle developing within 1 to 2 days after surgery. The patient has a painfully enlarged testicle that is hard in consistency and associated with low-grade fever. Pain is severe and may last several weeks. Ischemic orchitis is caused by thrombosis of the veins draining the testicle after extensive dissection of the spermatic cord. It is generally accepted that the incidence can be decreased by division of large inguinal–scrotal sacs leaving the distal sac open in situ rather than excising it.¹⁰⁰ The majority of patients with testicular swelling as an immediate complication of herniorrhaphy recover without testicular atrophy. In one report, testicular atrophy developed in 19 patients among 52,583 primary inguinal hernia repairs (0.036%) and 33 patients among 7,169 recurrent inguinal hernia repairs (0.46%).¹⁰¹ A substantial number of patients who develop testicular atrophy after inguinal herniorrhaphy have no history of a testicular problem at the time of the index operation. The management of a patient with ischemic orchitis is usually conservative with elevation and anti-inflammatory medication. Antibiotics and steroids have been used but their value is unproved.

Miscellaneous. Hydroceles occasionally develop after inguinal herniorrhaphy, but the cause is not known and therefore a preventative measure is not possible. The urologic literature suggests that the practice of leaving the distal aspect of an indirect inguinal sac in situ rather than removing it should be incriminated, but this is not accepted by most experienced hernia surgeons. The treatment is the same as for any other hydrocele. Testicular descent is a complication felt to be related to complete division of the cremasteric muscle, but the occurrence is variable. The cord structures lose their tethering effect, allowing the testicle to descend into the most dependent portion of the scrotum. Due to the elasticity of the scrotum, with time, gravity causes the scrotum to elongate. Patients complain their testicle “drops into the toilet” and can be quite unhappy. Few hernia surgeons now routinely completely divide the cremasteric muscle, so it is hoped that this will become a rare phenomenon. The dysejaculation syndrome is characterized by searing, burning, painful sensations throughout the groin around the time of ejaculation. The incidence is approximately 0.04%.¹⁰⁰

Wound Infection. This is a surprisingly rare complication of groin herniorrhaphy (<5%) and the reason for the “protected” status, especially when compared to prosthetic ventral herniorrhaphy, is not known.¹⁰¹ Most cases of necrotizing fascitis following inguinal hernia repair have been associated with

either strangulated bowel or appendicitis in the hernial sac. Necrotizing fasciitis has only previously been reported in a few cases following elective hernia repair. Other factors leading to infection are pre-existing infection or ulceration of the skin over the hernia, obesity, incarcerated or obstructed bowel within the hernia, and perforation of the bowel at the time of hernia repair. Untreated seromas can become secondarily infected. It is not always necessary to remove the mesh prosthesis in the presence of infection. A trial of local wound care after opening of the incision and debridement is warranted.

Seromas. Seromas are common with extensive flap dissection in large hernias and with the use of synthetic mesh in laparoscopic hernia repairs and are possibly related to the size of the mesh used. The fluid eventually resorbs spontaneously. Aspiration is performed for symptomatic relief only. Strategies to prevent and manage seromas are largely based on empiricism and personal opinion, as objective data are nearly absent.

Bleeding. Hemorrhage can occur from the cremasteric, internal spermatic, or inferior epigastric vessels. Conservative treatment with reassurance is preferred for a stable hematoma. Evacuation is rarely required. Injuries to the deep circumflex artery, the corona mortis, or the external iliac vessels may result in a large retroperitoneal hematoma.

Prosthetic Complications. Shrinkage of polypropylene and other meshes should be considered by surgeons when performing prosthetic repairs. The decrease in size is felt to be due to scarification of the recipient's tissue. Intestinal obstruction or fistulization is possible by erosion, especially if there is physical contact between intestine and the prosthesis. Rejection because of an allergic response is possible but extremely rare. What patients cite as "rejection" of the mesh is usually the result of infection. Local erosion into the cord structures has also been reported.¹⁰²

Complications Related to Laparoscopy

Vascular Injury. These are for the most part related to access. The most serious injuries occur to vessels that reside in the retroperitoneum. For all laparoscopic procedures, the risk for major vascular injury that requires operative intervention is 0.9 per 1,000 cases.¹⁰³ The vessels most at risk are the distal aorta, common iliac arteries and veins, and inferior vena cava and the inferior epigastric vessels. Injuries to the renal vessels have also been reported. These vessels are fixed and may be penetrated even if the safety mechanisms of the needle or trocar are working properly. The mesenteric and omental vessels are also at risk, especially in the presence of adhesions. The epigastric arteries may be injured with secondary cannula placement.

The insufflation needle is the most common cause of vascular injury but may be self-limiting; on the other hand, injuries caused by a trocar are usually more obvious and catastrophic. The mortality associated with retroperitoneal injury secondary to trocar insertion ranges from 9% to 36%, even with rapid identification and repair. When retroperitoneal trocar injury is suspected, immediate conventional laparotomy is almost always indicated. Most abdominal wall vascular complications occur during the placement of secondary cannulas. Usually, pressure can be applied to bleeding at the trocar site with the cannula. Occasionally, suture ligation is required, which has been simplified by the development of disposable "exit devices" designed to facilitate the placement of fascial sutures. Most of these complications can be avoided by placing the secondary trocars under direct vision.

Gas Embolism. This is caused by intravascular insufflation.¹⁰⁴ It is an uncommon complication, unique to the needle insufflation technique. Careful attention to tests confirming proper peritoneal needle placement will keep the incidence of this complication low.

Visceral Injury. Visceral injuries are uncommon, occurring in 1.8 per 1,000 cases of all laparoscopic procedures, but they have a mortality rate of 5%.¹⁰³ The most common means of injury is the insufflation needle. Simple repair laparoscopically is usually possible as most are self-limiting. If the injury is caused by a trocar, formal repair of the injury will be needed. The injury can be repaired laparoscopically if the skill of the laparoscopic surgeon is sufficient. Otherwise, laparotomy is mandatory. Quite often, these injuries go unnoticed at the time of insult, so that visceral injury is the most common cause of late morbidity and mortality associated with laparoscopic access. Patients typically present with peritonitis and sepsis 2 days to 1 week after surgery.

Bladder Injury. Bladder injury can be the result of a laparoscopic misadventure or can be directly related to the herniorrhaphy. Laparoscopic peritoneal access can result in a bladder perforation, usually the result of failure to decompress a distended bladder. Less commonly, injury is associated with a congenital bladder abnormality. Bladder injury has not been reported with the open access technique.

Injury to the bladder can also occur during secondary suprapubic trocar placement during the course of an operation. When bladder injury occurs, it is usually obvious. After Veress needle insertion, urine is withdrawn into the syringe, or blood and gas are noticed in the urine if the patient is catheterized. In questionable cases, methylene blue dye may be instilled into the bladder to look for leakage. Bladder injury recognized during laparoscopy should be repaired laparoscopically provided the experience of the surgeon is sufficient. This should be followed by bladder drainage for 7 to 10 days.

Bladder injury may present in a delayed fashion with hematuria and lower abdominal discomfort. A retrograde cystogram usually confirms the diagnosis. Small defects may be managed with postoperative decompression via an indwelling catheter for urinary drainage, while larger defects necessitate repair. The bladder is especially prone to injury during preperitoneal herniorrhaphies or when the preperitoneal space has previously been dissected (e.g., previous preperitoneal hernia repair or prostatectomy).¹⁰⁵

Bowel Obstruction. This problem plagued the developmental stages of laparoscopic inguinal herniorrhaphy for two reasons. First, the importance of closing trocar sites at the fascial level if greater than 5 mm was not appreciated, resulting in the occasional patient with an incarcerated or strangulated ventral hernia at the trocar site, leading to the clinical presentation of a bowel obstruction. There are now several different types of reusable and disposable appliances designed to facilitate trocar site fascial closure, which should minimize the incidence of these hernias. The second is inadequate peritoneal closure over the prosthesis, which allows bowel to migrate into the preperitoneal space, also resulting in intestinal obstruction. Steps taken to avoid tension at the peritoneal closure site (see TAPP technique section) have decreased this problem. Theoretically, the TEP procedure eliminates the possibility of this complication because the abdomen is not entered. However, inadvertent breaches of the peritoneum during a TEP herniorrhaphy are common, especially in patients with thin peritoneum or those who have scar tissue associated with previous lower abdominal surgery. These peritoneal lacerations can be difficult to recognize because they are not in the visual field of the limited working space, and indeed, intestinal obstruction has been reported.¹⁰⁶

Diaphragmatic Dysfunction. Phrenic nerve palsy has been reported with a variety of laparoscopic procedures; it is usually transient but has been known to require a short period of mechanical ventilation. Stretching during the pneumoperitoneum probably causes this complication.

Hypercapnia. This is the result of inadequate compensatory ventilation given the fact that, in the vast majority of laparoscopic procedures, carbon dioxide is used as the insufflating agent.

VENTRAL ABDOMINAL WALL HERNIAS

Repair of ventral abdominal wall hernia is one of the most common procedures performed by a general surgeon. Ventral hernias comprise a diverse group of hernias and are best divided into their various subtypes when discussing surgical management because the natural history as well as results of operations varies depending on the specific hernia. Table 72-9 uses the common terminology familiar to all surgeons for classifying abdominal wall hernias. Table 72-10 is a classification system published by Zollinger that expands upon Table 72-9 by further subdividing ventral hernias based on etiology.¹⁰⁷ An expert panel of European Hernia Society proposed a grid classification system of incisional hernias in based on localization, size, recurrences, and symptoms (Table 72-11)^{108,109} and the Ventral Hernia Working Group (VHWG)¹¹⁰ (Table 72-12) has proposed a grading system for ventral hernias based on

risk of post-operative surgical site occurrences.

UMBILICAL AND PERIUMBILICAL HERNIAS

Umbilical and periumbilical hernias are usually congenital, caused by arrest of the normal spontaneous closure of the umbilical ring through which umbilical blood vessels pass in the developing fetus, which results in a defect in the fascia covered by skin. In infants, the fascial defect varies in size but is most commonly 1 to 2 cm. A large proportion of pediatric umbilical hernias heal spontaneously, and 80% of them close by the time the patient is 2 years old. This is the only abdominal wall defect genetically

programmed to close. Persistent umbilical hernias require surgery. In older patients, the onset is usually sudden and the defect is relatively small. There are several syndromes associated with umbilical hernias such as mucopolysaccharide storage diseases, Beckwith–Wiedemann syndrome, and Down syndrome. Predisposing factors for the development of umbilical hernias in adults are multiple pregnancies, obesity, cirrhosis with ascites, and large abdominal tumors, all of which cause an increase in intra-abdominal pressure.¹¹¹ Male gender is also a risk factor with the peak incidence of repair at about age 60 years.¹¹² The differential diagnosis includes the varicosities that extend radially from the umbilicus in persons with portal hypertension, the so-called caput medusae (Fig. 72-31). The varicosities have a bluish discoloration and fill when the patient is straining. A metastatic deposit of intra-abdominal cancer at the umbilicus may mimic umbilical herniation. Cancer cells reach this area via lymphatics in the falciform ligament. Metastasis presents as a hard nodule, and biopsy is diagnostic. Other periumbilical masses that can be confused with an umbilical hernia include umbilical granulomas, omphalomesenteric duct remnant cysts, and urachal cysts.

Figure 72-31. Caput medusae. Large periumbilical collaterals in a patient with portal hypertension.

The management of umbilical hernias is nonoperative in children up to the age of 2 or 3 years because spontaneous closure is the rule. In those who require surgery, adults or children, the repair depends on the size of the hernia. An infraumbilical semilunar incision is made and the hernia identified. There may or may not be a true peritoneal sac, as smaller hernias usually consist of preperitoneal fat only. If a sac is present, it can be opened and the contents reduced into the abdomen. Alternatively, the hernia can be dissected circumferentially to the fascial opening and reduced without entering the peritoneal cavity. The dissection can be continued beneath the fascia creating a preperitoneal space for the placement of a prosthesis, if needed. Several techniques can be used to close the fascial defect. In 1901, James Mayo described the classic overlapping, vest-over-pants (double-breasting or waistcoat) technique, which bears the name of his clinic, in which the upper edge of the linea alba overlaps the lower edge (Fig. 72-32).¹¹³ The operation is losing popularity now because it is generally not consistent with the tension-free concept popular in hernia surgery today.¹¹⁴ It requires more dissection than other procedures to create the flaps and is therefore more painful. Simple suture herniorrhaphy is the easiest procedure but has the highest recurrence rate (especially with high body mass index [BMI] and smoking), and therefore should be used only for small defects. For larger hernias, particularly in adults, the preperitoneal space can be exploited by bluntly dissecting the peritoneum from the undersurface of the posterior rectus sheath for enough distance to be able to place an appropriate prosthesis. If the peritoneum is not entered, a mesh prosthesis is preferred, which is placed in the preperitoneal space and then the fascial edges closed if the defect is small enough. Otherwise, a bridging technique can be used with the fascial edges sewn to the underlying mesh. If the peritoneal cavity is entered, then a composite prosthesis (e.g., ePTFE + polypropylene) or a mesh prosthesis with an adhesion barrier (see prosthetic materials section) can be placed intraperitoneally with the adhesion barrier facing the viscera. A

laparoscopic approach for umbilical hernias is a good option for recurrent hernias or hernias with defects larger than 3 cm and, in retrospective reviews, has been shown to decrease operative times and result in faster recovery to normal activities. The technical details are similar to those of a laparoscopic incisional hernia repair (see incisional hernia section).

EPIGASTRIC HERNIAS

Epigastric hernias occur through a defect in the linea alba. In the majority of patients, only a single decussation of the fibers of the linea alba is present rather than the usual triple decussation (Fig. 72-7). The incidence of epigastric herniation reported varies from less than 1% to as high as 5%. Epigastric hernias are more common in woman than men with a peak incidence of repair around age 40 years.¹¹² About 50% of them are asymptomatic. Most are less than 1 cm and contain only incarcerated preperitoneal fat without a peritoneal sac. For this reason, epigastric hernias commonly cannot be visualized with laparoscopy. Patients complain of a painful nodule in the upper midline. Repair by reduction of the preperitoneal fat and simple closure of the defect is curative. These hernias are prone to recur, with rates as high as 10%, which has led many surgeons to routinely include a prosthetic underlay just as in umbilical or incisional hernias.

Left untreated, an epigastric hernia can become large enough for a peritoneal sac to form, into which the intra-abdominal contents can protrude. The sac is usually wide, and serious complications are not common. About 20% are multiple, and this needs to be ascertained prior to operation if all the defects are to be addressed, because after anesthesia induction, they can be difficult to identify.

In *diastasis recti*, the two rectus muscles are separated widely. The area of the linea alba is stretched and protrudes like a fin. The condition almost never produces complications and therefore surgical

correction is not routinely recommended. However, many patients find the defect unsightly and request treatment. They should be cautioned that many insurance companies consider this a cosmetic defect and will not reimburse. Surgery involves removal of a strip of the weakened linea alba and reapproximation. An alternative is a mesh repair done laparoscopically.

INCISIONAL HERNIAS

Incisional hernias occur as a complication of prior surgery. These hernias can follow any type of abdominal surgery, regardless of the type of incision. More than 2 million laparotomies are performed yearly in the United States, and the reported incidence of incisional hernia varies between 2% and 20%¹¹⁵ and is one of the most common reasons for reoperation.¹⁰⁹ The highest incidence is with midline incisions (10.5%) and transverse incisions (7.5%), but hernias are well documented following paramedian incisions as well (2.5%).¹¹⁶ The cumulative incidence of incisional hernias is linear, as they can present after considerable delay following the index operation. Poor surgical technique, rough handling of tissues, use of rapidly degraded absorbable suture materials, closure of the abdomen under tension, and infection of the wound are technical causes of incisional hernias. Morbid obesity, cigarette smoking, pulmonary disease, debilitation from cancer, chemotherapy, the use of steroids, hypoalbuminemia, and other pre-existing comorbid conditions are patient factors that have been incriminated. Patients with an aortic aneurysm or a proven defect in collagen metabolism also exhibit an increased incidence of incisional hernias.¹¹⁷ Read and Yoder in a retrospective review found that 17% of incisional hernias are incarcerated or strangulated at presentation.¹¹⁸ The consequences of unrepaired enlarging symptomatic hernias include loss of abdominal domain; significant biomechanical alterations that affect posture; compromise of activities of daily living, including lifting and straining; and poor cosmetics. Most of the published literature on treatment options addresses midline defects. The management of nonmidline incisional hernias (i.e., subcostal, transverse, or gridiron incisions) to some extent must be extrapolated.¹¹⁹

At least some ventral hernias can be prevented by proper abdominal closure after a laparotomy. Monofilament slowly absorbable or nonabsorbable sutures should be placed in the aponeurosis only 5 to 8 mm from the wound edge, not to include muscle, 4 to 5 mm apart in a single layer. Studies have shown that nonabsorbable sutures result in a lower incidence of incisional herniation but at the cost of increased wound pain and chronic suture sinuses when they become infected.¹⁰⁶ These suture sinuses tend to be multiple and take years to eradicate by probing the sinus tracks and removing deep sutures. The development of better monofilament absorbable sutures has caused most surgeons to use a slowly absorbable monofilament suture.¹⁰⁷ Using small needles is recommended to avoid including excessive amounts of tissue. By measuring the suture remnants in relationship to the total length of the suture, one can calculate a suture length to wound length ratio which should never be less than 4.¹²⁰

Another common practice after laparotomy is to prescribe abdominal binders. Although most surgeons prescribe abdominal binders following laparotomy, there is no evidence that these devices decrease pain; improve respiratory function; or prevent incisional hernias, seroma formation, or wound complications. The use of a binder may provide some comfort in the immediate postoperative period to some patients and may be recommended for this purpose only.^{121,122}

Massive Hernia

Although there is no consistent definition as to what constitutes a massive hernia, this term applies to abdominal wall hernias with a large portion of the abdominal contents situated within the sac and to hernias that are said to have “loss of domain” because the contents of the hernia exceed the capacity of the abdominal cavity. Many of these hernias are associated with morbid obesity, skin ulcerations, enterocutaneous fistulae, diverting stomas, and distortion of the abdominal wall from multiple prior attempts to repair them. Several physiologic changes such as alteration of ventilatory equilibrium and impairment of venous return results from long-standing massive hernias. Forced reduction of the hernia with replacement of contents into the abdominal cavity can increase intra-abdominal pressure considerably, resulting in respiratory insufficiency and cardiovascular compromise.¹²³ In extreme cases, it is impossible to return the contents to the abdomen and repair the hernia defect without resection of intra-abdominal contents, such as colectomy with omentectomy. Repair of massive ventral hernias with loss of domain is technically challenging and is associated with high morbidity, mortality, and recurrence rates. A good understanding of the abdominal wall anatomy and the nature of fascial defects

is essential prior to repairing these ventral hernias. Complications of repair are common and include respiratory compromise, abdominal compartment syndrome, skin flap necrosis, and wound infection, in addition to the usual surgical complications. Therefore, repair should not be recommended unless there are overwhelming indications such as disabling symptoms, bowel obstruction or strangulation, or extensive skin ulceration caused by the hernia. These patients might best be seen in centers with special interest in this area where teams have been assembled to treat complex abdominal wall pathologies.¹²⁴

Preoperative Preparation

The key to successful management of ventral hernia is good preoperative work-up. Many of these patients have had multiple prior surgeries including previous attempts at hernia repair and it is important for the surgeon to obtain and review all the previous operative reports and evaluate the nature of previous surgeries, incision types, and closure techniques. Smoking and obesity are major contributors to failure of ventral hernia repair. At our institution, we require 4 weeks of smoking cessation prior to elective ventral hernia repair. Morbidly obese patients are at increased risk for wound infection and dehiscence and should be managed in a multidisciplinary setting with the bariatric surgery team, and sometimes a staged approach may be needed with weight loss surgery initially with temporary repair of ventral hernia followed by definitive repair once the patient achieves maximal weight loss and has fewer comorbidities. Management of chronic wounds and infections (both local and distant), smoking cessation, optimization of cardiopulmonary and nutritional status, and control of blood sugars in diabetic patients is recommended prior to surgery also optimize the chances of a successful repair. Imaging studies in the form of CT scan of the abdomen and pelvis, although not routinely indicated, may be helpful for preoperative planning in patients with large or complex ventral hernias, posttraumatic hernias, morbid obesity, and special cases such as lumbar hernias. Functional cine MRI is a new technology that can be used to find postoperative adhesions.¹²⁵ A mechanical bowel preparation may be used in patients with complex ventral hernias. On the day of surgery, special attention must be paid to the administration of thromboembolism prophylaxis and preoperative antibiotics. An iodophor skin barrier may be used to decrease mesh contact with the skin. In the operating room, sharp debridement of devitalized or infected tissues is recommended and sometimes a staged approach for hernia repair is necessary. Prior to abdominal wall closure, attention should be paid to ventilator mechanics as rising peak and plateau pressures can be early signs of abdominal compartment syndrome.

Progressive Preoperative Pneumoperitoneum

Progressive preoperative pneumoperitoneum (PPP), which was first described for repair of giant incisional hernias, was described by Goni Moreno in 1940 and is a useful technique in these patients to expand the abdominal cavity by stretching the abdominal wall and the diaphragm.^{29,123,126,127} The maneuver involves injecting room air (or CO₂) via a needle or implantable catheter every 1 to 3 days to tolerance (development of shoulder pain, difficulty breathing, or subcutaneous emphysema). This can be performed by patients and families as outpatient, but some surgeons prefer to use pressure monitoring, keeping it less than 15 mm Hg. Although theoretically attractive, pneumoperitoneum is not always successful. The injected gas sometimes preferentially enters the hernia sac and distends it with minimal effect on the abdominal cavity. In addition, pneumoperitoneum has been shown to diminish lower extremity venous return. This could translate into a higher risk of thromboembolic complications.

PPP has been more commonly applied in Europe and South America with good results for large ventral hernias. In a recent study, safety and feasibility of this approach were shown in 16 patients.¹²³ Of these 16 patients, 7 still required an additional procedure such as ileocecectomy or lateral relaxing incision on the rectus sheath to achieve abdominal wall closure. In another small series consisting of 9 patients, PPP was sufficient to reduce the visceral contents, permitting a retrorectus repair in 80% of these patients.¹²⁸ Of 9 patients, 1 patient with diabetes mellitus developed an abdominal wall abscess requiring drainage in the postoperative period. Many surgeons in North America are skeptical about the approach, questioning how one ensures that the air injected stays in the peritoneal cavity and does not leak into the hernia sac, enlarging it further. Also of concern is the possibility of infection and the cost, especially if in-hospital monitoring is needed.

Tissue Expansion

Tissue expanders can also be used when either skin or the myofascial elements of the abdominal wall are deficient.¹²⁹ They are implanted subcutaneously or subfascially and are gradually inflated until the

desired amount of extra tissue is obtained. The limitation of the technique is the delay in definitive repair while the expansion is going on and the considerable amount of pain that patients complain of. The intra-abdominal placement of tissue expanders has also been described to address the issue of loss of domain, but this is primarily confined to the pediatric literature.

Visceral Resection

In certain circumstances, resection of intra-abdominal viscera is necessary to avoid causing increase in intra-abdominal pressure. Options include total omentectomy, subtotal colectomy, and removal of retroperitoneal fat.

Algorithm 72-4. Management of incisional hernia.

Treatment of Ventral Hernias

General Principles

8 As described above, the abdominal wall is a complex unit and plays an important role in respiration, defecation, micturition, movement of the trunk, and protection of intra-abdominal organs (Algorithm 72-4). It has been shown that health-related quality of life improves after ventral incisional hernia repair, presumably related to improved abdominal wall function.¹³⁰ Many experts believe that reapproximation of rectus muscles in the midline restores functional abdominal wall anatomy and is recommended if it can be performed without excessive tension.

Nonprosthetic Repairs

Traditionally, the repair of an incisional hernia depended on the size of the hernia. If the defect was solitary and 3 cm or less, primary closure with nonabsorbable suture material was recommended. This concept is now questioned after the publication of a landmark prospective randomized trial by Luijendijk and colleagues from the Netherlands in the year 2000 and updated in 2004 comparing a prosthetic repair versus primary suture.^{131,132} These investigators found a 50% reduction in the recurrence rate when a prosthesis was used, and this even applied to small hernias (<10 cm²). For this reason, a simple, nonprosthetic technique should be reserved for only the smallest hernias in patients without risk factors for further recurrence.

Component Separation

9 Abdominal wall reconstruction and component separation are useful tools in the armamentarium of the hernia surgeon. The main types of component separation techniques currently used are described below.

Anterior Component Separation. A more complex nonprosthetic repair is the component separation technique popularized in the early 1990s by Ramirez and colleagues which is based on lateral fasciotomies that allow sliding of the muscular fascia layers toward the midline providing coverage for

large midline abdominal wall defects.¹³³ Originally, it was proposed as a tissue repair for patients with contaminated wounds to avoid use of prosthesis, but several modifications have been described since the original description. In this technique, the skin and subcutaneous fat are dissected free from the anterior sheath of the rectus abdominis muscle and the aponeurosis of the external oblique muscle. The aponeurosis of the external oblique muscle is transected longitudinally just lateral to the lateral side of the rectus sheath (Fig. 72-33). It is important to extend the incision inferiorly up to the inguinal ligament and superiorly onto the chest wall at least 5 to 7 cm cranial to the costal margin especially for defects close to the xiphoid. The external oblique muscle is separated from the internal oblique muscle, as far laterally as possible in a relatively avascular plane, beyond the area of skin undermining toward the midaxillary line. This step is safe because the neurovascular bundle (comprising the intercostal nerves and vessels) lies deep to the internal oblique muscle. The result is that the internal oblique muscle and the rectus abdominis slide medially for about 7 to 10 cm. When necessary, 2 to 4 cm of additional length can be gained by performing a posterior rectus release, separating the posterior rectus sheath from the rectus abdominal muscle. This step may be difficult in patients who have scarring from previous surgical procedures. Care must be taken not to damage the neurovascular bundle that runs between the internal oblique and transversus abdominis muscle to enter the rectus sheath posterolaterally. After advancement of the rectus complex toward the midline, the fascial closure is performed followed by layered closure of the subcutaneous tissues and skin with drains. Several modifications to the original technique have been described. The technique can also be used as an adjuvant to the prosthetic repairs described next.

Posterior Component Separation. This technique is an extension of the posterior rectus release (Fig. 72-34).¹³⁴ Once the lateral aspect of the posterior rectus space has been developed, the posterior rectus sheath is incised just medial to the neurovascular bundles penetrating the rectus muscle so that they are not damaged (Fig. 72-35). This procedure should start cranial to the umbilicus which will then expose the underlying transversus abdominis muscle which is then incised along its medial edge: starting this dissection caudal to the umbilicus will lead to more difficulty getting into the appropriate plane because the transversus abdominis muscle has no muscle fibers in this region. This step allows entrance into plane between transversalis fascia/peritoneum and the transversus abdominis muscle (Fig. 72-36).

Figure 72-33. Component separation technique.

The dissection can then be extended laterally to the psoas muscle. The dissection plane can be extended cephalad to the diaphragm by dissecting dorsal to the sternum, sweeping the peritoneum/transversalis fascia off the diaphragm. Inferiorly, the dissection can be extended into the space of Retzius to expose the symphysis pubis and Cooper ligament. This dissection results not only in the creation of a large retromuscular space beyond the linea semilunaris but also allows for significant medial advancement of the posterior rectus sheaths which are then closed in the midline followed by placement of mesh in retromuscular plane and fixation with transabdominal sutures and possibly bone anchors. The anterior sheaths can then be reapproximated in the midline because the transverse abdominis release allows further medialization of the anterior sheaths or the gap can be bridged with mesh. This technique is an important addition in the armamentarium of surgeons dealing with complex abdominal wall problems and has been shown to have favorable perioperative morbidity and acceptable recurrence rates compared to anterior component separation.¹²¹ The technique is particularly suited for addressing recurrent hernias after a prior anterior component separation but probably should not be used simultaneously in combination with a concurrent anterior component separation. However, posterior component separation is technically difficult because the transversalis fascia/peritoneum complex posteriorly can be extremely thin, tearing easily. In order to isolate the viscera from the

prosthetic which will eventually be placed, these tears must be repaired. If this is not possible, one of the adhesion barrier prostheses should be used. A much easier dissection can be accomplished by not dividing the transversus abdominis muscle while continuing laterally in the plane between the transversus abdominis muscle and the internal oblique muscle.¹³⁵ But, this theoretically should denervate the muscle because the intercostal nerves travel to the rectus muscle in this plane (see anatomy section). This remains a controversial issue because another component separation technique known as the Memphis modification completely detaches the rectus muscle out of its bed after an external oblique release leaving only the cranial and caudal attachments intact in a manner similar to a tram flap.¹³⁶ This technique allows for a completely tension-free reapproximation of the rectus muscles in the midline. Because the authors do not report an excessive rate of either rectus atrophy or abdominal wall dysfunction, one must assume that the nerve supply accompanying the inferior and superior epigastric vessels is sufficient. In addition, this technique is probably best suited for patients who are not hernia formers but require medialization of the fascial gap after trauma.

Figure 72-34. The retromuscular space is developed by incising the posterior rectus sheath and dissecting the rectus abdominis muscle from the underlying rectus sheath.

Endoscopic Component Separation. This technique was developed to lessen the degree of abdominal dissection and potentially address the wound complications associated with open component separation with the use of a balloon dissector and laparoscopic instruments. The technique involves making 2- to 4-cm incisions just below the costal margin in anterior axillary line (lateral to the attachment of the external oblique aponeurosis on the rectus sheath). The space between the external and internal oblique muscles is dissected and under camera guidance, dissector balloon is inflated which further aids blunt dissection in this layer. The external oblique aponeurosis is then divided. A Balloon dissector can be used in the subcutaneous space as well. This technique can be followed by either open or laparoscopic hernia repair.^{137,138} One potential limitation might be the adequacy of the myofascial advancements using this technique. Proponents of this technique claim reduction in postoperative stay by about 50% and a distinct advantage in the setting of stomas, but it remains to be seen if it is effective in the long term (Fig. 72-32).

Figure 72-35. The posterior rectus sheath is incised about 0.5 to 1 cm medial to the anterior/posterior rectus sheath junction to expose the underlying transversus abdominis muscle. Note the perforator nerves that are preserved during retromuscular dissection and subsequent posterior component release.

Figure 72-36. Division of the posterior rectus fascia just medial to the linea semilunaris and perforator nerves followed by

Prosthetic Repairs

The concept of prosthetic use is not new as it was proposed by Usher and colleagues in 1958 for hernia repair using a polypropylene mesh.¹³⁹ Over the ensuing years, lessons have been learnt: (a) the use of absorbable mesh leads to a high relapse rate, (b) repetition of a previously inadequate technique frequently fails, (c) a simple inlay technique that bridges the defect has a high failure rate, (d) reinforcement of the entire scar is advisable irrespective of operative findings, and (e) the success of a mesh repair depends on the extent of overlap or underlap.¹⁴⁰

Numerous techniques for prosthetic incisional hernia repair have been described, which is not surprising since there are so many variables. For example, there are five potential spaces to place the prosthesis (Figs. 72-3 and 72-37).

Because of the number of different repairs, it is not practical to describe each one in detail. However, most of them represent a variation of one of the general classes described.

Onlay Prosthetic Technique. The basis of this procedure is to place a prosthesis over any of a wide variety of simple repairs. Although it has some proponents, many surgeons feel that this technique offers little advantage over the simple repair that the prosthesis overlies. This may be explained by Pascal's law which states that pressure exerted on an enclosed fluid acts equally in all directions. In an onlay technique, this results in lifting forces against the mesh.¹⁴¹

Figure 72-37. Potential spaces in the abdominal wall to place prosthetic material: onlay or on top of the anterior abdominal fascia; under the anterior fascia but in front of the muscle (if the mesh bridges that space, it would be an inlay technique); retrorectus space or the underlay technique below the muscle but above the posterior fascia; preperitoneal (important when below the arcuate line); intraperitoneal.

Figure 72-38. 1: Hernia defect with bulging sac. 2: Anterior fascia is incised longitudinally on either side of the defect. 3: The anterior fascia is then rotated medially, in effect lengthening the posterior sheath to allow primary closure, isolating the abdominal

Prosthetic Bridging Technique. A prosthetic bridging repair became popular in the 1990s in keeping with the tension-free concept for inguinal herniorrhaphy. The basic principle underlying this technique is that for a prosthetic repair to be effective, the defect should be bridged. Although this repair is theoretically attractive, it has not been nearly as successful for incisional hernias as for inguinal hernias. The recurrence rate is especially high in obese patients. It is not recommended but may be the last resort if the defect is so large that abdominal wall closure cannot be obtained even with sophisticated techniques such as component separation. One modification technique used for massive abdominal hernias is known as medialization which consists of closure of the abdominal wall with ePTFE followed by scheduled serial visits to the operating room to tighten the prosthesis by removing a strip in the middle and suturing the edges together. This technique allows definitive abdominal wall closure after a mean six serial visits.¹⁴²

Combined Fascia and Mesh Closure. This group of repairs combines features of the component separation technique (described below) with the tension-free concept. By incising the anterior fascia and rotating the medial edge toward the midline in continuity with the posterior fascia, the posterior fascia is effectively lengthened (Fig. 72-38). The posterior fascia is closed primarily, but the anterior fascia is bridged with a prosthesis.

Sublay Prosthetic Technique. The sublay prosthetic repair, sometimes referred to as the retromuscular approach, is characterized by the placement of a large prosthesis in the space between the abdominal muscles and the peritoneum (Fig. 72-17). It was popularized by Rives, Velamanta, Stoppa, and Wantz and is particularly suitable for large and multiply recurrent hernias when most of the abdominal wall must be reconstructed.^{124,143,144} It is considered the most effective conventional incisional hernia repair and therefore the one against which other procedures must be measured. Its major disadvantage is its need for wide undermining of the abdominal layers with the potential risk of devascularization of the abdominal wall or the creation of a large seroma, which later leads to infection. Suction drains are used by most surgeons, although the literature does not unequivocally support their use.¹⁴⁵

Figure 72-39. Perforating blood vessels supplying the rectus muscle.

The procedure is begun by excising the previous scar and dissecting the peritoneal sac of the hernia to the level of the fascia. Occasionally, the sac does not have to be opened and the procedure can be performed totally extraperitoneal. More commonly, the sac is thin and easily disrupted, making entrance into the peritoneal cavity inevitable. The posterior rectus sheath is opened on each edge of the hernia defect and dissected away from the undersurface of the recti to the lateral edge of the rectus sheath, with care being taken to prevent damage to the perforating blood vessels at the lateral side of the sheath (Fig. 72-39). The posterior rectus sheaths are then approximated to each other primarily (unless the peritoneum has not been opened). During this part of the procedure, flaps must be created by dissecting the skin and subcutaneous tissue off the underlying fascia laterally until enough tension is relieved to allow primary closure of the anterior rectus sheath. It is sometimes necessary to add component separation to further decrease the tension. A large mesh prosthesis (combined with ePTFE or an adhesion barrier if the approximation of the posterior rectus sheath is inadequate) is then placed in this space outside the repaired posterior sheath but beneath the recti. The mesh is secured in this position with several sutures directly to the posterior rectus sheath. An alternative is to use a suture

passer to pass the two tails of a suture placed on the lateral side of a prosthesis through the lateral edge of the rectus sheath through separate fascia openings. The suture is then tied in the subcutaneous tissue resulting in a secure anchoring of the prosthesis in the abdominal wall. If the subcutaneous tissue dissection from the anterior rectus sheath has not been too extensive, the sutures cannot be retrieved in the subcutaneous tissue and therefore the suture passer is pushed through the entire thickness of the subcutaneous tissue and then through a small stab incision in the skin. The suture is tied and the knot allowed to retract back into the subcutaneous tissue and the skin is approximated over it. The procedure is completed by reapproximating the anterior rectus sheaths, thus bringing the rectus muscles back to their normal configuration. The best long-term results are obtained when the anterior fascia can be closed bringing the muscles back together because of an improvement in abdominal wall mechanics. However, it is sometimes impossible to achieve this and the gap must be bridged with a prosthesis (Fig. 72-40).

Figure 72-40. Fixation of prosthesis to the peritoneal surface of the abdominal wall with the use of a suture passer. Step 1: The suture passer device with a heavy nonabsorbable suture is passed through a 3-mm stab incision in the skin at an oblique angle. The device and suture traverse the entire abdominal wall and then the prosthesis. Once the peritoneal cavity is entered, the suture is released and the passer is withdrawn back into the subcutaneous tissue. Step 2: The device is redirected at a different angle through the abdominal wall and prosthesis and the suture is grasped. Step 3: The suture is pulled out of the abdominal cavity so that the two free ends are extracorporeal. Step 4: The suture is tied with the knot resting on the fascia. The skin is then closed.

Role of Flaps and Grafts

The use of flaps and grafts is usually reserved for patients in whom a conventional component separation repair with a retromuscular prosthesis is not possible. Free fascia lata grafts, autodermal grafts, and pedicled or free vascularized flaps have been reported, but are reserved for the most complex abdominal wall reconstructions.

Laparoscopic Ventral Hernia Repair. This operation was developed in the 1990s as a natural extension as surgeons became trained in the laparoscopic method for many commonly performed abdominal procedures. The greatest value of laparoscopic surgery is that reapproximation of abdominal muscles can be performed and the “gold standard” sublay technique can be replicated by the intra-abdominal placement of a submuscular prosthesis, eliminating the need for the extensive abdominal wall dissection implicit in the conventional operation.⁵³ ePTFE has a long track record of safety with contact with intra-abdominal viscera, and the development of the adhesion barrier-coated mesh prosthesis has made intra-abdominal placement more attractive. Laparoscopic surgery provides several advantages including decreased blood loss, lower wound infection rates, decreased hospital stay, and patient preference.^{125,146} Improvements in wound complications and recurrence rates have not been consistently demonstrated. Seromas are more commonly seen with laparoscopic repair but these mostly resolve uneventfully without needing additional intervention. Certain absolute contraindications to laparoscopic ventral hernia repairs exist including patients with hemodynamic instability and bowel compromise.

Entrance to the abdominal cavity followed by adhesiolysis can be problematic for a surgeon performing a laparoscopic ventral hernia repair and devastating complications are possible, which is the Achilles heel of this operation. This is because patients with incisional hernias by definition have had previous abdominal surgery and the midline is commonly not usable for initial access because of a previous incision in the area. The surgeon must make an educated guess as to the least likely place for significant adhesions as well as be familiar with alternative access techniques away from the midline. Unrecognized visceral injury can be the consequence if extreme care about entrance and adhesiolysis is not maintained. These injuries commonly go undetected until the patient develops signs of septic shock because it is difficult to differentiate peritoneal signs from ordinary postoperative pain. This accounts for the significant mortality with this complication. Surgeons performing laparoscopic ventral hernia repairs must have the good judgment to abandon the procedure in the face of a hostile abdomen. Left or right upper quadrant, subcostally, is generally a safe access site for the initial port.¹²⁵

Once the abdomen has been safely entered and the adhesiolysis completed, the abdominal contents are reduced from the hernia defect under direct laparoscopic guidance. The number and location of the sites of cannula placement vary depending on the size and location of the hernia. Once all the hernia defects are identified, the operating surgeon must make a decision to either continue the procedure laparoscopically or convert to an open operation. In our opinion, multiple “swiss cheese defects” are the best indication for a laparoscopic repair. On the other hand, if there are only one or two defects with wide separation of the muscles, the laparoscopic repair is not as effective for two reasons: (a) the prosthesis will tend to balloon out through this defect, simulating a recurrence even though the hernia is technically repaired, and (b) abdominal wall dynamics are addressed more effectively if the muscles can be reapproximated. The muscles can commonly be approximated using a suture passer/trocar site closing device similar to that demonstrated in [Figure 72-40](#). Our group favors conversion to an open, conventional operation in situations where it is not possible to reapproximate the muscles, but this philosophy is not shared by all. Even in the event of conversion, laparoscopy can be used as a useful adjunct to perform initial adhesiolysis and to examine the closure at the end of the repair to ensure approximation of fascial edges and rule out any inadvertent injury to intra-abdominal organs from the repair.

If laparoscopic hernia repair is planned, after initial adhesiolysis and examination of the defect, the prosthesis is prepared by placing absorbable sutures extracorporeally around its circumference with long tails extending from the nonadhesion barrier side. It is then rolled up and introduced through the largest cannula. After it is unrolled, a suture passer is introduced into the abdomen to grasp each of the suture tails through a single stab incision but separate musculofascial openings in array, which corresponds to the previously placed prosthesis sutures ([Fig. 72-40](#)). The sutures can be tied extracorporeally and the knot allowed to retract back into the subcutaneous tissue of the stab incisions. The skin is then closed over them. It is important that the prosthesis be positioned onto the peritoneum so that it widely overlaps the hernia defect (4 to 6 cm, at least). The prosthesis is further secured to the anterior abdominal wall with staples, tacks, or sutures using the suture passer technique.

Table 72-13 European Hernia Society (EHS) Classification of Parastomal Hernias

EHS Classification Grid for Parastomal Hernia		Small <5 cm	Large >5 cm
Concomitant incisional hernia	No	Primary	Recurrent
	Yes		

PARASTOMAL HERNIAS

Parastomal hernia is an incisional hernia related to the presence of an ostomy which can have significant effects on the patients’ quality of life, physical and psychological well being, and health care resources.¹⁴⁷ The incidence of parastomal hernia varies with the type of the stoma (1.8% to 28% for ileostomy and 4% to 48% for colostomies).^{148,149} Studies designed with very careful follow-up suggest that a paracolostomy hernia develops in more than 50% of patients followed for longer than 5 years with most occurring in the first 2 years. The true incidence of parastomal hernias has been difficult to quantify given the lack of uniform definition of what constitutes a hernia, variable follow-ups, and inadequacy of physical examination to diagnose early occurrences.¹⁵⁰ Poor site selection or technical errors, such as making the fascial opening too large, excessive splitting and stretching of muscle fibers,

epigastric nerve denervation, placing a stoma in an incision, or emergency rather than elective creation of stoma, account for some of these hernias. Placing a stoma lateral to the rectus sheath is widely touted as a cause, but this is now being challenged. Obesity, malnutrition, advanced age, collagen abnormalities, postoperative sepsis, abdominal distention, constipation, obstructive uropathy, steroid use, and chronic lung disease also contribute. Other techniques for stomal construction, such as extraperitoneal tunneling, stapled ostomy, and prophylactic mesh reinforcement for permanent colostomies especially in the posterior sublay position have been suggested, but their role in prevention of parastomal hernias is uncertain given the lack of randomized controlled trials and good quality evidence. A classification system for parastomal hernias has been recommended based on the size and presence of a concomitant incisional hernia by the European Hernia Society (Table 72-13) which will help standardize the definition of parastomal hernias for future studies.¹⁵¹

Fortunately, patients tolerate these hernias well. Most of the parastomal hernias are asymptomatic and therefore can be treated conservatively. Fewer than 20% of patients with parastomal hernias have a complication that mandates repair, and life-threatening complications, such as bowel obstruction or strangulation, are rare. Routine repair is therefore not recommended. Table 72-14 lists possible indications. The three general types of stomal hernia repair are fascial repair, stomal relocation, and prosthetic repair, which can be performed either laparoscopically or open. Fascial repair involves a local exploration around the stoma site, with primary closure of the defect. This approach is associated with up to 75% recurrence rate¹⁵² and should be considered of historical interest only. Stomal relocation¹⁵⁰ is usually indicated in patients with other stomal problems, such as skin excoriation or suboptimal stomal construction. The major drawbacks of stomal relocation are the fact that a laparotomy is required, which in and of itself causes more morbidity than some of the other techniques, and that it exposes the patient to the risk of three new incisional hernias at (a) the old stoma site, (b) the laparotomy incision site, and (c) the new stoma site with reported recurrence rates ranging from 24% to 86%.

Table 72-14 Indications for Repair of a Parastomal Hernia

Pain

Whenever possible, a prosthetic repair should be considered as this appears to be the most effective, although few randomized trials have been performed to unequivocally prove this. Options for the location of mesh placement in parastomal hernia repair are as follows:

1. Onlay with the mesh placed anterior to the anterior rectus aponeurosis. A hockey stick incision is usually performed outside the boundaries of the patient’s appliance (Fig. 72-41). The skin and subcutaneous tissue are then undermined to identify the fascial defect, which is closed primarily and reinforced with a prosthetic onlay. The problem with this approach is that the undermining of subcutaneous tissue leads to seroma formation, which sometimes goes on to infection. Recurrence rates of up to 26% have been reported with this technique with a mesh removal rate up to 23%.¹⁵³
2. Inlay with the mesh placed to bridge the defect and sutured to the fascial edges. This alternative has, in multiple series, been shown to have the highest chance of recurrence and suffers from the seroma problem, as with the onlay.
3. Sublay with the mesh placed dorsal to the rectus muscle and anterior to the posterior rectus sheath or mesh placement between posterior rectus sheath and peritoneum has been described in small case series. Posterior component separation with retromuscular mesh positioning is a technique that has been described in patients with complex parastomal hernias which uses mesh to reinforce all “at risk”

areas for recurrence.¹⁵⁴

4. Intraperitoneal inlay mesh (IPOM). An intra-abdominal prosthetic repair eliminates the need for the abdominal wall dissection and is therefore becoming increasingly popular. It also enlists the mechanical advantage of placing the prosthesis on the peritoneal side of the abdominal wall.¹⁵⁵ The intra-abdominal approach is particularly suited for laparoscopy, and several techniques have been described.¹⁵⁶ This can be performed in two ways. (1) The Sugarbaker technique which involves securing the mesh over the entire fascial defect circumferentially except laterally where the bowel exits to create a mesh flap valve around the stoma. This decreases the amount of contact with the stoma, decreasing the chances of infection. (2) The Keyhole technique where a 2- to 3-cm cutout is made in the mesh for the ostomy while widely covering the defect. This can be tricky as too small of an opening can obstruct the enterostomy while too large of an opening can result in recurrence.

Figure 72-41. Repair of a parastomal hernia. **A:** Incision around hernia. **B:** Hernial sac is identified, the contents are reduced, and the peritoneum is closed. **C:** The edges of the fascial defect are reapproximated. **D:** The fascial repair is reinforced with polypropylene mesh, which is wrapped around the subcutaneous portion of the colon and sutured in place.

5. Laparoscopic repair of parastomal hernia. Laparoscopic repair of parastomal hernias has the advantage of avoiding a large incision while providing superior view of the defect and allowing for intraperitoneal mesh placement.¹⁵⁷ Currently described techniques of laparoscopic repair include: (1) modified Sugarbaker technique, (2) Keyhole technique, and (3) Sandwich technique which combines both these approaches. Reported recurrence rates range from 0% to 47% with infection rates up to 16%, conversion rates range from 0% to 15% and 10% rate of mesh explantation. The most common mesh used for laparoscopic repair is ePTFE which is inert and more resistant to adhesions and erosion compared to standard mesh.

Prophylactic Mesh Placement

Recent randomized controlled trials and a recent meta-analysis have shown that prophylactic implantation of both biologic and synthetic mesh in a preperitoneal or sublay position for both ileostomies and colostomies is safe and effective and may be associated with some of these studies showing a decreased incidence (15% vs. 52%) of parastomal herniation.^{158,159} Synthetic meshes are cost effective without added morbidity or mortality. These studies have had limitations such as small sample size, heterogeneous population, and variable follow-up. Prospective multicenter randomized controlled study comparing standard stoma creation to re-enforcement with porcine acellular dermal matrix showed similar incidence of parastomal hernia at 24 months in both groups. Further large scale randomized controlled trial with follow-up are necessary to identify specific group of patients in whom re-enforcement is essential and cost effective and to study long-term effects of this approach.¹⁵⁹

Figure 72-42. Spigelian hernia. A: Usual site of occurrence. B: Transverse section of abdominal wall showing site of defect.

UNUSUAL HERNIAS

Spigelian Hernia

A Flemish anatomist, Adriaan van der Spiegel, first described the semilunar line, which is the lower limit of the posterior rectus sheath. Also called the spontaneous lateral ventral hernia, a Spigelian hernia protrudes through an area of weakness just lateral to the rectus sheath and just below this line (Fig. 72-42). The hernia is usually interparietal, rarely penetrating the external oblique fascia, and therefore can be difficult to appreciate. Most of the time, this hernia appears below the arcuate line. This is an unusual hernia; only 744 cases have been described in the literature. The usual presentation is lower abdominal swelling just lateral to the border of the rectus muscle. Spigelian hernias often occur in elderly female patients. They are usually small, about 1 to 2 cm in diameter, although large hernias up to 14 cm in diameter have been described. Omentum and small or large bowel may enter the sac. Incarceration and strangulation are common complications of this hernia. Because the hernia is deep to the external oblique fascia, the clinical presentation may not be obvious. Pain and tenderness may be the only signs. Plain roentgenograms may show a bowel shadow in this area, and CT can demonstrate the defect well. Treatment is operative repair. A transverse incision is centered over the mass. The external oblique aponeurosis is split to reveal the protrusion. If a large sac is present, it is divided and sutured. The aponeurotic defect is triangular, with its base at or near the lateral border of the rectus muscle. The defect is closed by joining the separated transversus and internal oblique layers. Another option is a laparoscopic repair, done using an intra-abdominal or preperitoneal approach. Recurrence is uncommon.

Table 72-15 Types of Lumbar Hernia

Type	Description
Superior lumbar hernia of Grynfeltt	Occurs through a space between the latissimus dorsi, the serratus posterior inferior, and the posterior border of the internal oblique muscle
Inferior lumbar hernia of Petit	Occurs through a defect in the space bounded by the latissimus dorsi posteriorly, the iliac crest inferiorly, and the posterior border of the external oblique anteriorly
Secondary lumbar hernia	Develops as a result of trauma, mostly surgical (e.g., renal surgery), or infection; lumbar hernias were encountered relatively frequently in the past in cases of spinal tuberculosis with paraspinal abscesses

Lumbar Hernia

The lumbar region is the area bounded inferiorly by the iliac crest and superiorly by the 12th rib, posteriorly by the erector spinae group of muscles, and anteriorly by the edge of the external oblique muscle as it extends from the 12th rib to the iliac crest. The three varieties of lumbar hernia are described in Table 72-15. These hernias require repair if they are large, and because of the size of the defect, synthetic mesh is used. For the inferior lumbar hernia, a rotation flap of fascia lata can be used (Fig. 72-43).

Obturator Hernia

This hernia is the result of abdominal contents protruding through the obturator canal in the pelvis. This canal is the opening in the superior part of the obturator membrane covering the foramen formed by the union of the pubic bone and ischium, through which the obturator nerve, artery, and vein pass from the pelvic cavity into the thigh. A recent history of profound asthenia and weight loss is not unusual, which is most likely due to the loss of the protective fat in the obturator canal.¹⁶⁰ This may account for the fact that women, more often than men, are afflicted with this hernia because their broader pelvis results in a larger obturator canal. The diagnosis of an obturator hernia is difficult because it is rare and physical examination is rarely helpful because the associated mass is concealed beneath the adductor muscles of the thigh. The main symptom is intermittent pain. During repair, the defect is approached transperitoneally; the hernia is reduced and mesh placed over the defect. Depending on the expertise of the responsible surgeon, either a conventional open or laparoscopic operation is reasonable.

Figure 72-43. Technique of repair of inferior lumbar hernia.

Sciatic Hernia

A sciatic hernia is a protrusion of a peritoneal sac through the major or minor sciatic foramen (Fig. 72-44). These very rare hernias present with a swelling on the buttock. The sciatic nerve may be involved. A ureter can become obstructed if it is included with the herniated tissues. The treatment of these hernias is surgical. Both transperitoneal and transgluteal approaches have been described. A combination of the two is sometimes used. The defect usually requires a prosthetic mesh repair.

Supravesical Hernia

This hernia is anterior to the urinary bladder and forms when the integrity of the transversus abdominis muscle and the transversalis fascia fail, both of which insert into the Cooper ligament. The preperitoneal

space is continuous with the retropubic space of Retzius, and the hernial sac protrudes into this area. The sac of the hernia is directed laterally, emerges at the lateral border of the rectus muscle, and presents in the inguinal, femoral, or obturator region. It can also be associated with an inguinal, femoral, or obturator hernia. Treatment of this hernia depends on recognizing it at the time of groin exploration and reinforcing the defect.

A second variety of these hernias is known as an internal supravescical hernia. They are classified according to whether they cross in front of, beside, or behind the bladder (Fig. 72-45). Bowel symptoms predominate in patients with these hernias, and urinary tract symptoms develop in up to 30%. The treatment is surgical, and a transperitoneal approach is used through a low midline incision. The hernias can usually be reduced without difficulty. The neck of the sac should be divided and closed.

Interparietal Hernia

This hernia is one in which the hernial sac lies between the layers of the abdominal wall. It may be either *preperitoneal* (between the peritoneum and the transversalis fascia) or *interstitial* (between the muscle layers of the abdominal wall). The majority are inguinal, in which case they are designated *inguinal interstitial* hernias. An *inguinal crural* hernia occurs when the sac passes behind the inguinal ligament in the region of the femoral ring.

Figure 72-44. Sciatic hernia. 1: Suprapiriform. 2: Infrapiriform. 3: Subspinous.

The cause of these hernias appears to be related to congenital abnormalities; they have been associated with failure of the testis to descend, congenital pouches, and other abnormalities, such as absence of the cremaster and absence of the external abdominal ring.

The diagnosis of these hernias is difficult because no swelling of the abdominal wall is obvious unless the hernia is large. Pain is commonly the only symptom, and it is not unusual for patients to present with intestinal obstruction secondary to incarceration. CT, ultrasonography, and laparoscopy can be helpful in making the diagnosis. Not infrequently, the correct diagnosis is made only at operation. The defect is repaired according to the principles described for inguinal and incisional hernias.

Flank Hernia

Relaxation of lateral abdominal wall is an underrecognized consequence of the lateral flank incision which leads to a lateral bulge, mostly without an associated fascial defect, usually in patients who have undergone urologic, vascular, or neurosurgical procedures which result in transection of the intercostal nerves and resulting atrophy. In majority of these cases, patients mainly complain of asymmetric appearance, but sometimes they can have discomfort associated with organs getting trapped in the bulge and both these problems can hugely impact patients' quality of life.

Littre Hernia

Littre hernia is a groin hernia containing a Meckel diverticulum. These hernias sometimes also contain

the appendix. If the diverticulum is symptomatic or strangulated, then it is mandatory to resect it at the time of the hernia repair.

Figure 72-45. Internal supraventricular hernias.

Perineal Hernia

These hernias are more common in older female patients and are related to a lax pelvic floor. They are termed *anterior* or *posterior* according to their relationship to the transverse perineal muscle. The anterior hernias usually present as a swelling in the labium or lateral vaginal wall. The posterior hernias present between the rectum and the ischial tuberosity. Surgical repair requires a transperitoneal approach, and, if the opening is large, a prosthetic mesh repair is required.

Perivascular Hernia

These hernias present through defects between the inguinal ligament and the iliopubic bone. They are known by various eponyms according to their position. The hernia protruding through a defect in the lacunar ligament is *Laugier hernia*. The hernia protruding through the pectineal fascia is *Cloquet hernia*. The hernia extending anterior to the femoral vessels but behind the inguinal ligament is *Velpeau hernia*. The hernia behind the vessels is *Serafini hernia*. Lateral to the femoral artery are two hernias, the anterior one being *Hesselbach hernia* and the more posterior one *Partridge hernia* (Fig. 72-46).

Complications of Ventral Hernia Repair

The complications of abdominal wall hernia repair are not infrequent, and their incidence depends on the size and type of hernia defect, the type of prostheses used, and the repair technique employed. The complications of hernia repair can be categorized according to whether they are related to the patient, or the operative technique and are listed in Table 72-16. Except for the complications unique to laparoscopy, complications occur at similar rates in both laparoscopic and conventional procedures.

Figure 72-46. Perivascular hernias and their eponyms.

Complications Related to Patients

Ileus. Ileus can be seen with either the conventional or the laparoscopic procedure but is more common with the latter. Treatment is symptomatic, and spontaneous resolution is the rule. Nasogastric decompression is occasionally needed.

10 Recurrence. Several factors contribute to the poor results obtained in repairing incisional hernias. These include pre-existing comorbid conditions, including debilitation from cancer, morbid obesity, the use of steroids, and chemotherapy. Lateral detachment of the mesh and inadequate mesh fixation caused by mesh distraction is another important cause of recurrence and is more commonly seen in the inlay techniques.^{91,115} Historical recurrence rates of 30% to 40% following ventral hernia repair have been

dramatically reduced by modern TFRs.

COMPLICATIONS

Table 72-16 Complications of Herniorrhaphy

Related to Laparoscopy	Related to Herniorrhaphy
Vascular injury	Recurrence
Intra-abdominal	Neurologic
Retroperitoneal	Iliohypogastric
Abdominal wall	Ilioinguinal
Gas embolism	Genitofemoral
Visceral injury	Lateral cutaneous
Bowel perforation	Cord and testicular problems
Bladder perforation	Wound infection
Trocar site complications	Seroma
Hematoma	Hydrocele
Hernia	Hematoma
Wound infection	Wound
Keloid	Scrotal
Bowel obstruction	Retroperitoneal
Trocar or peritoneal closure site hernia	Osteitis pubis
Adhesions	Prosthetic complications
Diaphragmatic dysfunction	Contraction
Hypercapnia	Erosion
Related to Patient	Infection
Urinary infection	Rejection
Ileus	Pain
Nausea and vomiting	
Aspiration pneumonia	
Cardiovascular and respiratory insufficiency	

Surgical Site Occurrences. Surgical site occurrences include superficial, deep, and organ space surgical site infections (SSIs) and wound dehiscence. The incidence of surgical site infection for incisional hernia is in the range of 10% to 15%, and is probably related to wound ischemia due to the required flap dissection. Other factors leading to infection are pre-existing infection or ulceration of the skin over the hernia, obesity, incarcerated or obstructed bowel within the hernia, and perforation of the bowel at the time of hernia repair. Risk models developed for predicting SSI risk include the Ventral Hernia Risk Score (VHRS) and the Hernia Wound Risk Assessment Tool (HW-RAT) using preoperative patient characteristics, operative factors, and wound characteristics which identify patients at increased risk for surgical site occurrences and can be used to guide clinical decisions and patient counseling (Table 72-17; Fig. 72-47).^{161,162}

Seromas. Seromas are common with extensive flap dissection in large ventral hernias and with the use of synthetic mesh in laparoscopic hernia repairs and are possibly related to the size of the mesh used. The fluid eventually resorbs spontaneously. Aspiration is performed for symptomatic relief only.

Bleeding. Bleeding and postoperative hematomas are common complications of hernia repair. Adequate hemostasis should be ensured especially if large flaps are raised to prevent this complication. Hematomas, like seromas, tend to get infected and should be monitored closely.

Prosthetic Complications. Shrinkage of polypropylene and other meshes should be considered by surgeons when performing prosthetic repairs. Sufficient overlap anticipating a 20% contracture is accepted by most. The decrease in size is felt to be due to scarification of the recipient's tissue. Intestinal obstruction or fistulization is possible by erosion, especially if there is physical contact between intestine and the prosthesis. Intra-abdominal placement of a mesh prosthesis should be avoided in favor of ePTFE or perhaps a biologic prosthesis whenever possible. Rejection because of an allergic response is possible but extremely rare.

Complications Related to Laparoscopy

These complications have been described above and include gas embolism, visceral injury, bladder injury, bowel obstruction, diaphragmatic dysfunction, and hypercapnia.

Table 72-17 HW RAT Breakdown of Risk Factors for Wound Complications

Risk Grouping	Risk Factors	Risk Score	
Mild risk factors (+1)	Diabetes	1	
	COPD	1	
	Class I obesity	1	
	45–64 yrs old	1	
	Intra-abdominal procedure	1	
Intermediate risk factors (+2)	Smoking	2	
	ASA physical status >2	2	
	Panniculectomy	2	
	Clean-contaminated wound	2	
	Partially dependent functional status	2	
	Low albumin	2	
	<45 yrs of age	2	
	Operative time 43–71 (min)	2	
Moderate risk factors (+3)	Totally dependent functional status	3	
	Inpatient operation	3	
	Class III obesity	3	
	Component separation	3	
Severe risk factors (+4 or more)	Contaminated wound	4	
	Operative time (71–117 min)	4	
	Dirty/infected wound	5	
	Operative time (>118 min)	6	
HW-RAT	Risk Score	Number of Patients (%)	Incidence of SSO (%)
1	0–10	16,097 (59.6%)	538(3.3%)
2	11–13	5,784 (21.4%)	536 (9.3%)
3	14–16	2,861 (12.3%)	472(14.2%)
4	17–19	998 (21.7%)	217(21.7%)
5	>19	812 (3.0%)	215 (26.5%)

Chapter 73

The Spleen

Giorgos C. Karakousis and Douglas L. Fraker

Key Points

- 1 The spleen relates to the diaphragm both superiorly and laterally, and it generally spans the 9th, 10th, and 11th ribs along the left mid to posterior axillary line.
 - 2 Accessory spleens are small nodules of splenic tissue that are completely separate from the main body of the spleen. Accessory spleens are important in disease processes in which a complete removal of all splenic tissue is mandatory for long-term cure such as certain autoimmune disorders.
 - 3 The primary hematologic function of the spleen is removal of senescent erythrocytes or remodeling of abnormal red blood cells, and the recycling of iron by splenic macrophages.
 - 4 The immunologic function of the spleen is to generate an immune response to antigens that are identified and cleared from the blood system.
 - 5 The spleen is the most common intra-abdominal organ injured by blunt trauma in the United States.
 - 6 The pathophysiology of immune thrombocytopenic purpura (ITP) is development of an IgG antibody to a platelet antigen. For patients who have failed medical therapy, an elective splenectomy may be recommended.
 - 7 Hypersplenism is a physical enlargement of the spleen that can occur because of neoplastic disorders, hematopoietic disorders of the bone marrow, and metabolic or storage disorders. In neoplastic disorders, the spleen is infiltrated and enlarged by leukemia or lymphoma cells.
 - 8 The types of organisms that account for infection are typically encapsulated organisms (most commonly *Streptococcus pneumoniae*).
-

The spleen has been a mysterious organ throughout surgical and medical history with a clear understanding and appreciation of its function only emerging in the latter half of the 20th century. The reasons for this paucity of knowledge on the spleen are multifactorial. The spleen has no obvious function that can be discerned from its anatomical structures or features; there are no clear relationships of gross pathology of the spleen to many of the diseases for which it is important; and, even in present time, it is difficult to obtain a biopsy of the spleen, thereby limiting the amount of tissue available for pathologic study. The diseases (other than trauma) in which the spleen has importance are generally of a hematologic or immunologic nature. Understanding of the normal physiology and subsequent pathophysiology of the spleen is important for surgical decision-making regarding when to recommend splenectomy and whether a partial splenectomy is possible. The only surgical procedure applied for the treatment of splenic disorders for the majority of history was splenectomy. Current variations on that procedure include laparoscopic splenectomy, partial splenectomy, and other spleen-preserving procedures. The history of surgery for the spleen, its anatomy and physiology, and the relevant disease processes as well as operative techniques are reviewed.

HISTORY

The spleen has had a colorful history based on the function ascribed to this organ by many of the prominent scientists throughout the ages (Table 73-1).¹ Even the origin of the English term “spleen” is unclear. It is felt to come from the Greek “splen” which may have been derived from the Greek word “splanknon,” meaning a viscus, or the Greek word “spaw,” which means to draw.² The dark purple red color led ancients to believe that the spleen may draw spoiled or bad parts of the blood to itself which predates one of the major roles of the spleen as a filtration device for senescent red blood cells. In ancient Greece, the spleen was felt to be the source of black bile that was one of the four cardinal humors related to melancholy.² However, ancient authors wrote in the Talmud that the spleen was the

seat for laughter and removal of the spleen would limit mirth in that person.² It was felt that the spleen was a source of discomfort sometimes felt as “a stitch in the side” for athletes and that by removal or ablation of the spleen an individual would run faster. Reports of the earliest procedures on the spleen indicate that runners in ancient Greece may have had their spleens ablated in an effort to improve their performance. This hypothesis was studied in an experimental model almost 2000 years later in 1922 at Johns Hopkins University, in which splenectomized mice versus control mice were evaluated for their ability to run a race and the splenectomized mice were reported to be faster.²

During the Renaissance, scientists began to question the various roles ascribed to splenic function. Paracelsus rejected the black bile theory and questioned whether the spleen had any meaningful role at all in the early 16th century. One of his students named Zaccarella reportedly performed the first splenectomy in the year 1549 in Palermo, Italy, removing the large spleen of a 24-year-old woman successfully.² This organ was reportedly displayed in the town square after this landmark but unsubstantiated procedure. Versalius during that same era performed splenectomy in mice and other animals and determined that the spleen was not essential to life as there was no clear difference following removal. Around this time in 1581, Viard performed what is felt to be perhaps the first splenic-preserving procedures, removing a portion of the spleen in two patients in which the organ had prolapsed through an abdominal wound. The first authenticated splenectomy was performed in Germany in 1826 by Carl Frederick Quitterbaum in a patient with secondary hypersplenism due to cirrhosis. This high-risk patient succumbed 6 hours after the procedure. The first successful operation in which the patient survived was performed by Jules Pean in France in 1865 for a large splenic cyst. This patient was operated on for what was thought to be an ovarian cystic mass, but it was found to be arising from the inferior portion of the spleen and required splenectomy for removal and the patient survived. In this early period of splenic surgery, there was much pessimism due to the high operative mortality rate primarily from hemorrhage. A collective series published in 1877 reported 50 splenectomies with a 70% overall mortality rate. By 1900, Bessel-Hagen reported 360 splenectomies with a 40% mortality rate. An in-depth discussion of the spleen in literature, art, and history was recently published by Morgenstern.³

Table 73-1 Historical Milestones in Surgery of the Spleen

1549	First reported splenectomy by Zaccarella in Italy
1826	First documented splenectomy by Quitterbaum in Germany
1865	First successful splenectomy by Paen in France
1892	First trauma splenectomy by Reigner in Germany
1911	Elective splenectomy for autoimmune hemolytic anemia
1916	Elective splenectomy for immune thrombocytopenia purpura
1952	First report of overwhelming postsplenectomy sepsis
1962	First report of splenic salvage procedure for trauma
1991	Laparoscopic splenectomy

The 20th century brought technical advances in terms of hemostasis and blood transfusion as well as an understanding of the pathophysiology of splenic function.⁴ The spleen was identified as the site of red cell destruction in autoimmune hemolytic anemia by Micheli in 1911. Paul Kaznelson, who was a Czech medical student, postulated that the removal of the spleen in patients with idiopathic thrombocytopenic purpura would be of benefit and, in 1916, he reported the successful treatment of a patient with that disease with splenectomy. Throughout the 20th century, as the understanding the pathophysiology of hematologic and immune disorders associated with the spleen increased, it became clearer the roles for splenectomy that are pertinent to modern-day practice.

EMBRYOLOGY AND ANATOMY

1 The spleen develops from the mesoderm as an outpouching from the mesogastrium during the 5th week of gestation⁴⁻⁶ with the natural rotation of the gut during subsequent development placing the

spleen in its typical position in the left upper quadrant of the abdomen (Fig. 73-1). In that location, the spleen relates to the diaphragm both superiorly and laterally, and it generally spans the 9th, 10th, and 11th ribs along the left mid to posterior axillary line. The ventral surface of the spleen relates to the greater curvature of the stomach and the tail of the pancreas. The tail of the pancreas touches the splenic capsule in 30% of cases and is 1 cm away in 70% of cases. The inferior pole relates to the left kidney posteriorly and the splenic flexure of the colon anteriorly.

The normal size of the spleen is approximately 13 × 7 × 4 cm.⁵ The typical weight of a spleen in a young adult is felt to be 150 to 200 g and this decreases to approximately 100 g in the elderly population (Fig. 73-2).^{7,8} It is felt that the spleen must double in size to the range of 300 to 400 g to project below the costal margin to allow palpation of the spleen tip on abdominal examination in a patient undergoing deep inspiration.⁹ The weight assigned to the spleen in defining massive splenomegaly has been arbitrarily set at 1,500 g or 10 times the average adult splenic weight. There can be a significant cleft in the capsule of the spleen that may be confused with splenic disruption on CT scan obtained for trauma.

Figure 73-1. Anatomic relation of the spleen to the liver, diaphragm, pancreas, colon, and kidney. The stomach is sectioned to illustrate the anatomic relation in situ.

Figure 73-2. A: The lateral or diaphragmatic surface of the spleen, showing the lobulated edge and the glistening capsule. B: The hilar surface of the spleen, showing the ligatures on the cephalad short gastric vessels and the caudal hilar vessels.

The vascular anatomy of the spleen is rather straightforward.¹⁰ The splenic artery is one of the three major trunks along with the left gastric artery and common hepatic artery branching off from the celiac axis (Fig. 73-3). This artery has a characteristic appearance on celiac arteriograms as a serpentine artery with loops extending both superiorly and inferiorly. There are several small pancreatic branches that supply blood to the body and tail of the pancreas along the lengths of this vessel. The first major splenic branch occurs approximately 2 to 3 cm from the hilum and it is called the superior polar artery. The main artery then divides into anywhere between three and five segmental branches that enter along the trabeculae of the spleen. Additional blood supply to the spleen comes from the left gastroepiploic artery via the short gastric vessels. When the spleen is massively enlarged, it may have direct vessels that are parasitized from the omentum, diaphragm, or the mesentery of the splenic flexure of the colon. The splenic artery generally travels outside the parenchyma of the pancreas just at the superior border although loops that go inferiorly may be completely covered by the posterior surface of the pancreas whereas superior loops may be well away from the pancreatic surface. It is these more cranially located curves that are the optimal place to provide a ligature for control of the splenic artery during procedures in which there is significant thrombocytopenia or for enlarged spleens. These are generally areas that have few pancreatic branches and avoid proximity to the splenic vein that occurs when the artery loops inferiorly.

The splenic vein is formed by segmental venous branches that leave the trabeculae and coalesce into the main splenic vein in the hilum of the spleen (Fig. 73-3). The splenic vein is intimately associated with the posterior surface of the tail and body of the pancreas to its junction with the superior mesenteric vein forming the portal vein. The inferior mesenteric vein may join the splenic vein directly at several areas along its course or may come together right at the junction of the superior mesenteric vein. There are again several pancreatic branches that directly enter this splenic vein. The blood flow to the spleen in the typical adult is estimated to be 200 to 300 mL/min or approximately 5% of the cardiac output.¹⁰

The lymph node drainage generally follows the vasculature. The primary lymph nodes are located in the hilum of the spleen and also along the splenic artery at the superior border of the pancreas and along the short gastric vessels.

There are several ligaments that maintain the spleen in its fixed position in the left upper quadrant (Fig. 73-4).⁶ Three of these ligaments are virtually always present (except in the condition of the “wandering spleen”)¹¹ and two may be present to variable extents, depending on the individual patient and the disease process. The first ligament that is constant is the splenogastric ligament that is a left-sided superior extension of the greater omentum along the proximal greater curvature of the stomach. Within this area supplied by the left gastroepiploic vessels are short gastric vessels that branch to the

upper pole of the spleen and often provide the upper two-thirds of the spleen with alternative blood supply. The second and very important ligament is the splenorenal ligament that runs parallel to the posterolateral border of the spleen and attaches this to the superior pole of Gerota fascia developing the left kidney. This ligament is divided when mobilizing the spleen during splenectomy and allows reflection of the spleen with or without tail of the pancreas medially. The splenocolic ligament is short and may be avascular or have small blood vessels that go from the inferior tip of the spleen to the splenic flexure of the colon. This may be divided by cautery or may have vessels that need controlled with ties or clips during mobilization of the splenic flexure of the colon.

Two ligaments that are variably present are the spleno- omental attachments and the splenophrenic attachments (Fig. 73-4). The free part of the greater omentum may have variable association with the splenic capsule along the inferior pole. There are often small vessels that may be controlled by electrocautery. This attachment may be absent or may be quite extensive over the lower pole of the spleen. It is this attachment to the omentum that often leads to disruption of the capsule along this inferior pole causing bleeding in other abdominal procedures and may even eventually result in splenectomy for control with an inadvertent injury. Before exerting inferior traction on the omentum during any procedure, the extent of attachments to the lower pole of the spleen should be investigated and, if present, should be divided prior to more vigorous mobilization. There may be direct ligaments connecting the spleen to the diaphragm identified as splenophrenic ligaments. These typically are present to a greater degree when the spleen is diseased or enlarged. They may be avascular or may have branches of vessels parasitized from the diaphragm blood supply especially with large spleens.

Figure 73-3. The arterial blood flow to the spleen is derived from the splenic artery, the left gastroepiploic artery, and the short gastric arteries (vasa brevia). The venous drainage into this portal vein is also shown.

The anatomy of the spleen itself is segmental being fed by arteries and drained by veins that leave via the trabecula.¹² The trabeculae are fibrous bands that attach to the splenic capsule. The parenchyma of the spleen in between these trabeculae is divided into a small area of white pulp surrounding the arteries, a marginal zone, and the larger predominant area of red pulp that comprises 75% of the splenic parenchyma.^{13,14} The capsule of the spleen is quite thin as it is only a few cells layers thick. This consists of a single layer of mesothelium and several layers of fibroelastic tissue. In other mammals but not humans, there may be variable amounts of smooth muscle in the capsule. This smooth muscle would allow contraction and mobilization of the circulating blood cells that are stored in the spleen.¹⁵ The trabecular arteries that enter the spleen as continuation of the segmental arterial branches then give off perpendicular branches to form the central arteries (Fig. 73-5). Surrounding these central arteries is the

periarterial lymphatic sheath that is composed of T lymphocytes as well as follicles with B cells at various stages of development. During the antigenic stimulation, this area greatly expands with more mature and secondary follicles. The marginal zone is the borderline between the white pulp and the red pulp and contains a mixture of lymphatics and macrophages. The structure of the red pulp is made up of splenic cords with an intervening area called splenic sinuses. The splenic cords, also known as the cords of Billroth, are a meshwork of fibroblasts and a large number of mature macrophages. The splenic sinuses are an interconnective meshwork of fairly random red cell spaces that are thin walled and generally filled with large numbers of erythrocytes.¹⁴

Figure 73-4. The relations of the spleen to the abdominal and retroperitoneal viscera are seen in a cross section of the left-facing torso.

Figure 73-5. The splenic microanatomy is shown with depictions of both the open and closed circulations.

Studies on blood flow show two alternative routes to the spleen being fast flow and slow flow.¹⁶ A small proportion of the blood goes through the splenic arteries and returns rapidly to the splenic veins. This fast flow pattern consists of a greater predominance of plasma and few erythrocytes because of streaming and accounts for only 10% of flow. A particularly large portion of the erythrocytes that enter the spleen travel through the highly fenestrated meshwork in the red pulp as part of the filtration process of the spleen. This slow path or slow flow comprises up to 90% of the splenic blood flow and relates to the role of the spleen in clearing senescent erythrocytes.

2 Accessory spleens are small nodules of splenic tissue that are completely separate from the main body of the spleen. They typically range in size from 0.5 cm up to 3–4 cm. The reported incidence of accessory spleens ranges between 10% and 20%. The most common location for these small nodules of splenic tissue is in the splenic hilum, the omentum most commonly between the stomach and transverse colon but also within the greater omentum, and the small bowel mesentery. However, they can occur virtually anywhere in the abdomen including the retroperitoneum behind the spleen and in the pelvis. Accessory spleens are important in disease processes in which a complete removal of all splenic tissue is mandatory for long-term cure such as certain autoimmune disorders. A preoperative nuclear medicine spleen scan may also be helpful in some circumstances to identify sources of residual splenic tissue,¹⁷

particularly when present in less common locations.

PHYSIOLOGY

The major functions of the spleen can be divided into two general categories of hematologic functions and immunologic functions (Table 73-2).¹⁴ For hematologic functions, the spleen primarily is an organ related to the destruction or clearance of the circulating blood cell elements as a normal physiologic mechanism. This physiologic filtration function is increased in disease states that produce hypersplenism. The spleen may play a minor role in hematopoiesis and storage of blood cells that can be mobilized for the circulation with the predominantly stored cell being platelets predominantly platelets. In terms of the immunologic functions, the spleen relates to the vascular system in many of the same ways that lymph nodes relate to the lymphatic system. The white pulp and marginal zones are most important for the immunologic functions, whereas the red pulp is primarily related to the hematologic functions. However, the macrophages that line the cords or fill the cords in the red pulp are clearly also important for immunosurveillance for intravascular pathogens.

Table 73-2 Normal Functions of the Spleen

Hematologic
Culling or destruction of senescent erythrocytes
Pitting or removal of cytoplasm inclusive in erythrocytes
Reservoir for platelets and granulocytes
Hematopoiesis – as fetus or in conditions with bone marrow destruction
Immunologic
Filtration and trapping of circulatory antigens
Lymphocyte stimulation and proliferation
Antibody production in germinal follicles
Production of opsonin-tufts in and properdin
Opsonins: tufts in and properdin

3 The primary hematologic function of the spleen is removal of senescent erythrocytes or remodeling of abnormal red blood cells with various deformities and the recycling of iron by splenic macrophages.¹⁴ The average life span of a normal erythrocyte measured on clearance studies in humans is estimated to be approximately 120 days.¹⁸ It is also estimated that the spleen destroys approximately 100 billion erythrocytes daily in the red pulp. The process of removal or phagocytosis of erythrocytes or other blood cells is called culling. The blood flow patterns of the spleen lead to a hemoconcentrated erythrocyte-laden fluid that enters the sinuses of the red pulp. Here a slow flow through the sinusoid network with adjacent macrophage filled cords leads to the environment in which erythrocytes may become trapped and then phagocytized by the macrophages. The precise mechanism by which senescent red cells are identified for destruction in normal physiology is unclear. One hypothesis would be that over the course of the life span of an erythrocyte, there is loss of either membrane elements or total membrane material such that the red cells become less compliant and therefore become trapped in the mesh of the sinusoids. A second hypothesis is that specific cell surface marker molecules may become either more exposed or less available to allow identification of senescent cells targeted for destruction. Pathologic destruction of red cells occurs in diseases such as hereditary spherocytosis or elliptocytosis in which genetic defect creates abnormal red cell pliability limiting its passage through the red pulp. Similarly, in sickle cell anemia, the genetic defect in the hemoglobin alters red cell shape and creates destruction with clogging of the sinusoids. A second pathologic mechanism in which destruction of red cells is increased is in disease processes in which there is an increase in red pulp volume, a condition known as hypersplenism.

The second physiologic process involving circulating erythrocytes is remodeling or pitting that is partial removal of the cell membrane typically associated with the cytoplasmic inclusions. Erythrocytes with a remnant of the cell nucleus remaining pass more slowly through the splenic red pulp because of their larger size.¹⁴ The nuclear remnant may be trapped passing through a small space in the spleen and this solid particle that does not allow deformation gets pinched off in the process of pitting. Intracytoplasmic inclusions include Howell–Jolly bodies that are nuclear remnants, Heinz bodies that

are denatured hemoglobin, and Pappenheimer bodies that are iron granules.

The destruction of the other circulating cellular elements of the blood (platelets and leukocytes) is more in the realm of pathophysiology of the spleen than normal physiologic function. The disease processes in which these cells are removed are related to either autoantibodies to cell surface elements or hypersplenism. If either platelets or white blood cells become coated with antibodies, the Fc portion of the immunoglobulin will interact with the Fc receptors on the macrophages in the splenic cords leading to phagocytosis of these cell types. With splenic enlargement from various causes of hypersplenism, a similar process of destruction may occur even without any autoantibodies or defects in the cells just because of an increase in splenic mass.

The spleen serves as a potential source for hematopoiesis of all cell types during gestation. In normal humans, there is felt to be very little if any production of red cells, granulocytes, or platelets, which is not the case in other mammals. In the white pulp of the spleen, there are germinal centers with amplification and production of reactive lymphocytes. The cords of the spleen are filled with macrophages and throughout normal adult life there may be production of lymphocytes and macrophages in the spleen. In certain disease states, the spleen may develop the capacity for erythropoiesis and myelopoiesis. The best example is agnogenic myeloid metaplasia (AMM), discussed in more detail later. In this disease, the bone marrow is replaced with fibrotic scar and a portion of the hematopoietic function of the marrow is taken over by the spleen that is typically quite enlarged.

The final hematologic function of the spleen may be as a reservoir of circulating cellular elements.¹⁵ In humans, the only significant cell type that is stored in the spleen is platelets and it is estimated that 30% of all platelets may reside in the spleen. This function may be more important than other mammals particularly those with significant smooth muscle lining the capsule of the spleen that allows contracture with expulsion of large numbers of stored cells as a physiologic response to injury.

4 The immunologic function of the spleen is primarily to generate an immune response to antigens that are identified and cleared from the blood system. Either opsonized antigens or specific encapsulated microorganisms are important examples of target antigens trapped by the spleen. The spleen is an ideal environment for generation of either a cellular or humoral immune response. There are all of the necessary cells types for stimulation of the immune response including phagocytic cells, dendritic cells, T cells, and B cells that may form general follicles to generate specific antibody responses. These interactions primarily occur in the marginal zone in the white pulp that may become quite enlarged and hypertrophied during antigen stimulation. These cellular components and the structure of the germinal follicles are essentially identical to those found in lymph node tissue that becomes enlarged in a similar way with antigenic stimulation via microbes or antigens in the lymphatic system.

The spleen is also involved in nonspecific immune responses. It is the site of synthesis of both properdin and tuftsin that are opsonins. Tuftsin is a small peptide that binds to the surface of granulocytes and promotes phagocytic function by these cells.¹⁹ Properdin can initiate the alternate pathway of complement activation that may be important in destruction of abnormal cells or bacteria that are antibody bound. The spleen is not the only source of these nonspecific immune-enhancing proteins and therefore splenectomy may lead to only a modest alteration in this function.

PATHOPHYSIOLOGY

There are characteristic responses that share many common features under the broad category of hyposplenism and hypersplenism. These features highlight the normal physiologic functions of the spleen and provide guidelines and influence clinical decision-making when managing patients after splenectomy or in deciding which patients should undergo splenectomy.

Hyposplenism

By far, the most common cause of hyposplenism is surgical removal.²⁰ Other explanations would be an unusual situation of a congenitally small or absent spleen or acquired destruction of splenic tissue as occurs in sickle cell anemia or celiac disease. The diagnosis can be verified by ⁹⁹Tc-labeled spleen scan or pitted red blood cell count. Pathophysiologic consequences of hyposplenism or the changes seen after a splenectomy are predictable from the known functions of the spleen. There are hematologic changes in the circulating cells that can be predicted from the splenic functions of culling, pitting, and as a reservoir for platelets (Table 73-3). There are changes in the immunologic responses that are important primarily in infants or young children, which can lead to the problem of overwhelming postsplenectomy

sepsis. There are a variety of other causes for hyposplenism listed in [Table 73-4](#).

Table 73-3 Hematologic Changes Postsplenectomy/Hyposplenic Condition

1. Erythrocytes
Howell–Jolly bodies (nuclear fragments)
Heinz bodies (hemoglobin deposits)
Pappenheimer bodies (iron deposits)
Target cells
Spur cells (acanthocytes)
2. Platelets
Transient thrombocytosis
3. Leukocytes
Transient leukocytosis
Persistent lymphocytosis
Persistent monocytosis

The changes in circulating blood cells after splenectomy in cases of hyposplenism affect the erythrocytes, leukocytes, and platelets. Over time, the intracytoplasmic inclusions in the red cells that are normally cleared by the spleen accumulate resulting in presence of Howell–Jolly bodies, Heinz bodies, and Pappenheimer bodies as well as target cells with excess red blood cell membrane and occasionally increase in the circulating nucleated red blood cells or reticulocytes. As the spleen is the organ of storage for a large proportion of the platelets, a splenectomy often results in thrombocytosis with platelet counts postsplenectomy ranging between 500,000 and up to one million in some cases. This increased platelet count tends to be transient and may be a reflection of the fact that the spleen while being a storage organ for platelets may not be a primary area of platelet destruction after the typical half-life of 10 days. The immediate response after a splenectomy in white cells is leukocytosis again reflecting storage of a large proportion of white cells in the spleen.²¹ As with the thrombocytosis, this effect is transient but there may be long-term increases in the proportion of circulating lymphocytes and monocytes after the splenectomy. Preserving even a small amount of spleen can preserve splenic function in clearing senescent blood cells.²²

Clinical sequelae of hyposplenism or following splenectomy are discussed in more detail at the end of this chapter.

Hypersplenism

Hypersplenism is increased splenic function that is manifested clinically by the decrease in one or more of the circulating blood elements. The specific criteria for hypersplenism are: (1) documented anemia, thrombocytopenia, or leukopenia; (2) normal compensatory response by the bone marrow to correct the cytopenia; and (3) correction of this cytopenia by splenectomy. Some definitions of hypersplenism may also include the criteria for splenomegaly. This more restrictive definition would not necessarily incorporate, however, diseases or disorders related to abnormalities in circulating blood cells such as immune thrombocytopenic purpura (ITP) or autoimmune hemolytic anemia. The second approach to categorizing hypersplenism is to classify the disorders on the basis of whether the primary abnormality is in the circulating blood cells versus in the spleen itself ([Table 73-5](#)). For either situation, the pathophysiology is that the spleen is the site of destruction for one or more circulating blood elements. In cases of significantly enlarged spleen, additional symptoms relate to mass effect from the spleen on adjacent organs. The most important symptom is early satiety and weight loss as the stomach is compressed between the liver and the enlarged spleen. There are a variety of causes of hypersplenism that are typically neoplastic but may be related to primary blood cell dysfunction or abnormalities or other condition such as portal hypertension due to cirrhosis or splenic vein thrombosis. Hypersplenism is the most important indication for elective isolated splenectomy²¹ to reverse the cytopenia and often to relieve compressive symptoms from splenomegaly.

Table 73-4 Causes/Disorders Associated with Hyposplenism

Splenectomy
Sickle cell anemia
Congenital asplenia (autosomal recessive disorder)
Autoimmune disorders (e.g., glomerulonephritis and SLE)
Celiac disease/inflammatory bowel disease
Tumor or cystic replacement of spleen
Amyloidosis
Splenic vascular accident
Radiation

SLE, systemic lupus erythematosus.

Table 73-5 Causes of Hypersplenism

I. Primary diseases of blood cells; normal spleen
A. Congenital
i. Erythrocyte abnormalities
a. Hereditary spherocytosis
b. Hereditary elliptocytosis
c. Glucose 6 phosphate dehydrogenase deficiency
d. Pyruvate kinase deficiency
ii. Hemoglobin abnormalities
a. Thalassemia major
b. Sickle cell anemia (eventually results in splenic infarction and hyposplenism)
iii. Platelet abnormalities
a. Wiskott–Aldrich syndrome
B. Acquired
i. Autoimmune hemolytic anemia
ii. Autoimmune neutropenia – Felty syndrome
iii. Immune thrombocytopenia purpura
iv. Thrombotic thrombocytopenia purpura
II. Primary disorders of the spleen
A. Neoplastic
i. Hairy cell leukemia
ii. Chronic lymphocytic leukemia
iii. Chronic myelogenous leukemia
iv. Non-Hodgkin lymphoma
B. Cellular infiltrative (hematopoiesis)
i. Agnogenic myeloid metaplasia
ii. Mastocytosis
iii. Chediak–Higashi
C. Metabolic infiltration
i. Gaucher disease
ii. Sarcoidosis
D. Vascular
i. Splenic vein thrombosis
ii. Portal vein hypertension (cirrhosis)

SURGICAL TREATMENT FOR DISEASES RELATING TO THE SPLEEN

Until fairly recently, the only pertinent operation to discuss in relationship to disease involving the spleen was open splenectomy. Appreciation of the increased risk of infection in inpatients who are asplenic or hyposplenic in the late 1960s and the early 1970s led to two new surgical procedures. First, there was an interest in splenic preservation in cases of trauma with procedures including splenorrhaphy and other types of ways to save damaged spleen. Second, procedures to do partial splenectomy were developed primarily for elective surgery in which hypersplenism existed but a complete splenectomy was not necessary and there were advantages to partial splenectomy. The most recent change in surgery of the spleen relates to the explosion in the minimally invasive surgery that has happened over the past 25 years.²³ The spleen is very susceptible to a laparoscopic excision and recent reports have utilized laparoscopic splenectomy for virtually all indications including to remove massive spleens. Despite its increasing utilization in most major centers, though, laparoscopic splenectomy still appears to constitute only a minority of the splenectomy procedures performed nationally.

Indications for Splenectomy

To better describe and understand operative indications in surgery of the spleen, one could categorize splenectomy or procedures of the spleen into eight general areas:

- 1. *Trauma* or injury to the spleen.
- 2. *Autoimmune/erythrocyte disorders*. In this category of disease, there are specific cytopenias related to antibodies targeting platelets, erythrocytes, or neutrophils with the second category of diseases related to intrinsic structural changes within the erythrocyte. For these disorders, total splenectomy is typically indicated for cure.
- 3. *Hypersplenism* results in decreased circulating blood cells often including all subtypes of platelets and red blood cells. Hypersplenism may be related to neoplastic infiltration of the spleen or infiltration with lipids and other stored products that lead to massive spleen. Hypersplenism may cause symptoms due to the splenic size.
- 4. *Incidental splenectomy*. The spleen may be removed as part of a standard operation to remove the distal pancreas most commonly, and also for proximal gastric cancers due to the direct or nodal involvement. Other enlarged tumors of the left upper quadrant and retroperitoneum such as sarcoma and adrenal tumor, and left-sided renal cell cancers, may require splenectomy because of association of these tumors with the spleen or its vessels.
- 5. *Iatrogenic splenectomy*. This is a category that may be underreported but includes splenectomy or splenic preservation procedures due to inadvertent injury to the spleen during surgery for other reasons within the general abdominal cavity or, specifically, the left upper quadrant.
- 6. *Diagnostic procedures*. This category of splenectomy includes cases when the spleen is removed primarily to make a clinical diagnosis when none is available.²⁴ A subcategory of this would be staging laparotomy for Hodgkin disease that is rapidly becoming more of a historical footnote as the treatment of this lymphoma now rarely requires splenectomy.
- 7. *Vascular abnormalities*. Splenectomy for vascular events or abnormalities includes patients with splenic vein thrombosis or less commonly splenic artery aneurysms.
- 8. *Miscellaneous procedures*. This would include treatment of simple and neoplastic cysts, echinococcal cysts of the spleen, and treatment of the symptomatic “wandering spleen,” a congenital anomaly.

An estimated 22,000 splenectomies are performed annually in the United States.²⁵ Two recent reports have been published describing 10-year experiences for all splenectomies done in their respective institutions. The first report is the combined series of 1,280 splenectomies over a 10-year interval from the Barnes Hospital in St. Louis and the Brigham and Women’s Hospital in Boston.²⁴ The second report is a single institution over the identical time period from Vanderbilt University.²⁶ In the Barnes/Brigham series, there were 1,280 splenectomies, and in the Vanderbilt series there were 896 splenectomies (see Table 73-6). One can see that dependent on the type of institution and referral patterns, the indications for splenectomy vary to some degree. In the Vanderbilt series, the majority of splenectomies are done for trauma, which account for 41.5% of all operations done in that institution. In the Barnes/Brigham & Women’s series, the most common indication was incidental splenectomy in which the spleen was removed as part of an excision of another organ, typically large tumor somewhere in the left upper quadrant of the abdomen. The second most frequent indication for splenectomy was staging laparotomy for Hodgkin disease. This is likely to be different in the ensuing decade as both treatment indications and diagnostic techniques have significantly eliminated this practice after 1990. These differences highlight that indications for splenectomy can vary dramatically among centers, in part related to trauma volume at the centers and cancer case referrals. It also should be noted that if one eliminates the traumatic, incidental, and staging procedures, the most common indication in both series relates to autoimmune or erythrocyte disorder.

Table 73-6 Indications for Splenectomy in Two Large Series From Academic Medical Centers

	Barnes/Brigham & Women's ²⁸	Vanderbilt ²⁹
N	1,280	896
Dates	1986–1995	1986–1995
Trauma	167 (13.0%)	372 (41.5%)
Autoimmune/erythrocyte disorders	219 (17.1%)	140 (15.6%)
Hyperplasia	99 (7.7%)	138 (15.4%)
Incidental	336 (26.3%)	110 (12.3%)
Iatrogenic	NA	33 (8.1%)
Diagnostic unknown	122 (9.5%)	18 (2.0%)
Diagnostic staging for Hodgkin disease	258 (20.2%)	NA
Vascular	74 (5.8%)	21 (2.3%)
Miscellaneous	5 (0.4%)	24 (2.7%)

Table 73-7 Grading of Splenic Injuries

Grade	Laceration	Hamartoma
I	<1 cm in depth	Subcapsular <10% of surface
II	1 to 3 cm in depth not involving a trabecular vessel	Subcapsular 10–50% of surface area or 5 cm in diameter
III	>3 cm depth or any depth involving a trabecular vessel	Subcapsular >50% of surface area or intraparenchymal
IV	Segmental or hilar vessel involvement	
V	Shattered spleen or hilar vessel disruption	

The details of the indications for splenectomy in each of these categories are discussed. The specific indications for splenectomy (whether total or partial), the alternative treatments that are available, and the results from surgical removal of the spleen are also reviewed.

Trauma of the Spleen

5 The spleen is the most common intra-abdominal organ injured by blunt trauma in the United States and in many institutions splenectomy remains the most common operative procedure performed on the spleen.²⁷ The history of splenic surgery mirrors the history of surgery for trauma. In the ancient medical literature, there have been reports of resection of portions of the spleen that had herniated through a flank wound.²⁸ The first documented splenectomy for penetrating trauma occurred in San Francisco by a British naval surgeon named O'Brien in 1816 when a spleen protruded out the side of a knife wound.¹² In the late 19th century, Theodor Billroth observed during an autopsy of a patient who died of head trauma 5 days earlier that there was minimal blood in the peritoneum from the fracture of the splenic capsule and predicted that these injuries might be managed operatively. Although in the earlier part of the 20th century, splenic trauma was uniformly managed by a complete splenectomy, Dr. Campos Christo of Brazil reported partial splenectomy and splenic salvage for both penetrating and blunt trauma in 1962 (Table 73-1).⁴ This initial report, combined with the ability to obtain repeated cross-sectional imaging and with the understanding of splenic function, has led to the current management guidelines of nonoperative management for lower-grade splenic injuries and operative management centered around splenic preservation when possible.²⁹

The most common modes of blunt injuries leading to splenic rupture are motor vehicle accidents as well as bicycle accidents in which upper abdominal trauma may occur. The signs and symptoms of isolated splenic injury include tenderness in the left upper quadrant of the abdomen. Attention must be directed towards the lower lateral left ribs; focal tenderness over ribs 9 through 11 in that region should raise suspicion of possible splenic injury. Approximately 20% of cases of rib fracture can be demonstrated on radiographs. Patients may have referred pain to the left shoulder (Kehr sign) particularly when placed in the Trendelenburg position with palpation of the upper abdomen. The spleen itself is rarely palpable but when a left upper quadrant mass is palpable, it likely represents a contained hematoma or a subcapsular hematoma (Ballance sign). Depending on the severity of the injury, patients may have no hemodynamic instability or may be in frank hypovolemic shock. The grading system for splenic trauma is summarized in Table 73-7.

The diagnostic studies associated with splenic rupture would potentially include a decrease in hematocrit and hemoglobin although initial assessment before volume resuscitation may show normal

levels. After a short period of time there is often a leukocytosis in the range of 15,000 to 20,000. Plain abdominal x-ray films, in addition to possibly showing left rib fractures, may show displacement or a corrugated appearance along the greater curvature of the stomach due to a hematoma infiltrating the gastrosplenic ligament (Fig. 73-6). Peritoneal lavage will reveal the presence of blood in the abdomen. The most important current tool for diagnosis particularly in patients who are hemodynamic stable enough to be managed conservatively is the CT scan. Contrast CT scan will show the splenic contour and will also show the amount of extrasplenic blood (Fig. 73-7).³⁰

Overall blunt injuries comprise the majority of splenic trauma, but the spleen is susceptible to penetrating trauma in the retroperitoneum, lower thoracic penetrating trauma, or upper abdominal penetrating trauma. A 15-year state review of splenic trauma in Pennsylvania reported 10,652 (92%) blunt injuries and 893 (8%) penetrating.²⁹ The management and diagnosis of penetrating injuries trauma of the thorax and upper abdomen are less of a diagnostic dilemma as a majority of these patients undergo abdominal exploration because of associated injuries. In some series, there are additional injuries in 90% to 100% of patients with penetrating trauma to the spleen and 40% to 60% associated injuries in cases of blunt trauma.

Figure 73-6. Abdominal film in a patient with a splenic rupture from blunt trauma with a perisplenic hematoma displacing the greater curvature of the stomach medially. The scalloped appearance is indicative of blood in the gastrosplenic ligament (radiograph courtesy of Dr. C. William Schwab).

Figure 73-7. A contrast CT scan on a patient with splenic rupture near the hilum. There is considerable blood in the perisplenic fossa as well as free blood in the peritoneal cavity around the liver (radiograph courtesy of Dr. C. William Schwab).

Management of splenic injuries historically has been a laparotomy with splenectomy. Since Christo introduced the ability to do either partial splenectomy or splenorrhaphy, there has been an increased trend with surgical procedures to try to repair or preserve part, if not all, of the spleen. The current trend in management is a nonoperative approach with observation in serial CT scans.³¹ The presence of peritonitis, associated injuries requiring surgery, overall injury severity, evidence of hypovolemic shock with ongoing bleeding, and the patient's age are the primary factors that are taken into consideration while deciding on nonoperative versus operative management of blunt splenic injuries.²⁹ If patients have diffuse peritonitis or if patients have hypotension related to hypovolemic shock, urgent laparotomy is indicated (Fig. 73-8). There have been increasing reports of splenectomy successfully performed laparoscopically for blunt splenic trauma³²; however, a minimally invasive approach is typically used very selectively in this setting, given the frequent hemodynamic instability and concurrent injuries that may be better addressed via laparotomy. For patients who are hemodynamically stable and do not have other injuries that require surgical management, the recommendation is to attempt nonoperative observation of these patients.

The standard nonoperative management protocol would include very close observation in an intensive care unit or a similar monitored environment. Patients would have serial abdominal examinations as well as serial hemoglobin and hematocrit assessments. Any change in status in which patients remain otherwise relatively stable would be evaluated with a follow-up CT scan to see if there is progressive or ongoing bleeding demonstrated by increased hemoperitoneum or expansion of splenic hematoma. A recent report noted that routine follow-up CT scans did not alter management in patients treated nonoperatively.³³ Only patients with changes in hemodynamic parameters had a change in management. With this conservative management, the majority of patients would avoid laparotomy for isolated splenic blunt trauma.³⁴ If patients are older, have associated injuries, or have ongoing blood loss, a laparotomy is appropriate for blunt splenic trauma.^{28,35} Again, the nature of the splenic injury is graded relative to the degree of damage to the splenic parenchyma and the proximity to the splenic hilum and major blood vessels (Table 73-7). The principles of operative management would include stopping ongoing hemorrhage while preserving the maximal amount of viable splenic parenchyma. Nonviable or devascularized tissue must be debrided.³⁶ Partial splenectomy has been popularized on the basis of the concept of segmental blood supply via the trabecular arteries. A variety of approaches can be taken to more minor peripheral splenic trauma including primary repair or mesh repair (Fig. 73-9). Utilization of multiple material that are available for hemostasis including microfibrillar collagen, thrombins of gelfoam, or fibrin glue sealants have been utilized to obtain control of splenic hemorrhage. The argon beam coagulator is a very useful instrument for capsular tear or evulsions. Of note, all of these techniques that have been applied to patients with blunt trauma can be similarly applied to patients who have inadvertent trauma to the spleen during operations for other reasons (surgeries involving dissection of the splenic flexure of the colon or the left kidney, adrenal gland, or stomach).

Figure 73-8. A,B: Rapid mobilization of a bleeding spleen can be accomplished in most patients by blunt dissection of the lateral attachments. C: The splenic hilum can then be quickly controlled.

Figure 73-9. A: Techniques to suture superficial splenic lacerations. B: Technique to control bleeding after hemisplenectomy. The sutures can be interlocked. C: Polyglycolic acid mesh sheets or mesh bags can be applied to spleens that have had the capsule stripped away.

Over the past decade, this trend towards non-surgical management has expanded, with increasing success rates noted with conservative management. A recent study of more than 625 patients with blunt trauma over the past decade compared with the prior decade showed that there was an increase in initial nonoperative management from 61% to 85%.³⁷ The success rate of nonoperative management increased as well from 77% to 96% and the splenic salvage rate from 57% to 88%.³⁷ This may be partly due to a decreased distribution of more severe splenic injuries and partly the result of an increasing trend toward the use of embolization of splenic arteries as part of the nonoperative management of blunt trauma. A recent systematic review of 16,490 patients with blunt splenic trauma reported that for severe splenic trauma, nonoperative management was associated with a decreased mortality rate as compared with operative management (4.8% vs. 13.5%).³⁸ However, the higher mortality rate observed in the group managed operatively appeared could be explained by the presence of other concurrent injuries in that group. The authors concluded that, while nonoperative management remains the recommended approach by the American Association for the Surgery of Trauma for grade I and II injuries, the data for managing more severe splenic injuries are very heterogeneous with multiple potential confounders, making it more difficult to interpret.

Since its introduction in the early 1992 as a potential maneuver to improve the nonoperative management of blunt splenic injury, embolization with either coils or gelfoam of either proximal or distal splenic vessels has had increased utilization,³⁹ extending into the management of selected grade 3 or 4 injuries. In the study comparing the outcome of blunt trauma over the past two decades, the use of embolization increased from 2.7% to 22.6%.³⁷ The majority of studies provide similar data that the overall success rate for nonoperative management with splenic artery embolization is improved and could decrease the use of blood products.⁴⁰ There have been some recent studies stating that this may be overutilized and a report of a failure rate of 27% in patients with embolization failed and needed surgical exploration.⁴¹ Again, these comparative studies are not matched in terms of severity of injury

or even the techniques used for the splenic artery embolization.

One corollary with the nonoperative management of blunt splenic trauma is the risk of delayed rupture. Standard guidelines of conservative management are that patients should have stable hemoglobin for 36 to 48 hours and have resolution of abdominal pain prior to discharge. The delayed rupture rate in a large series of more than 1,900 patients showed that 27 patients were readmitted for splenectomy within 180 days of discharge,⁴² a delayed rupture rate of 1.4%. The median time from injury to readmission for splenectomy was 8 days with the range of 3 to 146 days. Similar results were obtained in an institutional study of 450 patients with nonoperative management of blunt splenic injury. In this group, 4% failed with eventual splenectomy due to delayed rupture.⁴³ Both studies stress that with the increased use of nonoperative management, the potential risks of delayed rupture require very specific discharge instructions to patients regarding reonset of acute abdominal pain with other signs and symptoms of hypotension requiring emergent transportation to the nearest emergency room or hospital facility.

Another area of splenic trauma is atraumatic splenic rupture. This can be considered more spontaneous rupture and it occurs primarily with enlargement of the spleen with malignant disorders either primary or secondary metastases, infectious disease, or inflammatory diseases, or technical disorders such as pregnancy or peripartum rupture. In a large series of more than 900 patients with atraumatic spontaneous rupture of the spleen, only 6.4% had no pathologic or mechanical causes that were identified.⁴⁴

Autoimmune/Erythrocyte Disorders

There are two categories of disease in which abnormalities do not originate in terms of the histology, pathology, or size of the spleen but rather are due to either autoimmune phenomenon or intrinsic diseases within circulating cells that lead to their destruction. The most common and obvious example of this is ITP in which antibodies to platelet antigens lead to destruction of platelets and thrombocytopenia with the spleen being the primary source of platelet elimination. Related diseases affecting erythrocytes and neutrophils with specific antibodies and splenic elimination occur to lesser degrees.

A second category of disease is not an autoimmune phenomenon but rather an intrinsic cellular defect that leads to a shortened half-life of this specific blood cell within the circulation primarily to elimination within the spleen. As discussed in the physiology section given earlier, a normal role of the spleen is to eliminate senescent erythrocytes and the anatomic structures of splenic circulation are well suited to that task. If erythrocytes are altered in terms of their structure, this may lead to more rapid elimination. In other diseases, genetic differences in the hemoglobin may result in splenic changes particularly in the setting of hypoxia that occurs within the splenic sinusoids. The most obvious example of this would be sickle cell anemia. A final example is an alteration in the cellular adhesion molecule that leads to increased interaction and thrombocytopenia in the Wiskott–Aldrich syndrome.

Immune Thrombocytopenic Purpura

ITP is often a diagnosis of exclusion once all other causes such as drug-induced thrombocytopenia or evidence of bone marrow failure are eliminated.⁴⁵ ITP is a disease characterized by autoimmune destruction of platelets with clinical manifestations of thrombocytopenia manifest by susceptibility to easy or excess bleeding.⁴⁶ ITP may be classified into an acute form and a chronic form. Acute ITP generally occurs in children younger than 8 years following an upper respiratory viral illness. The majority of children with acute ITP will have spontaneous remissions, whereas only a small minority of adults who develop ITP have remission and most go on to develop chronic ITP. This disease is usually self-limited and requires surgical intervention only in the case of intracranial bleeding. Chronic ITP accounts for the vast majority of cases considered for splenectomy. Similar to autoimmune hemolytic anemia, this disease may be idiopathic or may be secondary to a lymphoproliferative disorder, connective tissue disorder such as systemic lupus erythematosus, or drug or bacterial exposure. The average age at diagnosis is in the fourth decade of life and it affects women more commonly than men. As HIV was identified in the mid-1980s, it was noted that patients with acquired immunodeficiency syndrome (AIDS) were developing disease virtually identical to ITP.⁴⁷ AIDS patients with newly diagnosed ITP and risk factors for HIV should undergo screening.

6 The pathophysiology of ITP is development of an IgG antibody to a platelet antigen. This is felt to be most commonly directed against the fibrinogen receptor (glycoprotein IIb/IIIa and IR/IX).⁴⁸ The spleen plays a predominant role in this disease as it may be the site of initial antibody production.⁴⁹ It is

almost certainly the site of continued antibody production, and in the majority of patients the spleen is the primary site of platelet destruction. Since the targeted antigen is an intravascular cell, and since the spleen stores large numbers of platelets, it is felt that the initial reaction to the platelet cell antigen may occur in the spleen. Studies on antibody levels have indicated that overall IgG production in spleens from patients with ITP is markedly increased over individuals with normal spleens. Similarly, following splenectomy the amount of IgG antibody is somewhat decreased. The spleen is also the predominant site of platelet destruction. As noted earlier, the macrophages located in the cords of Billroth have receptors for the Fc portion of the IgG and will bind and phagocytize the antibody-coated platelets. A second more recently described component of the pathophysiology is an inappropriately decreased level of production of thrombopoietin for that level of thrombocytopenia. Cloning of the thrombopoietin receptor or the megakaryocytes has led to several new agents that can alter this aspect of the pathophysiology of ITP.^{50,51}

To be considered to have ITP, the platelet count has to at least be $<100,000$, but typically patients do not become symptomatic unless platelet counts are $<50,000$. Platelet counts in this disorder may drop to very low levels, well below 10,000 on occasion. Assays are now available to identify the IgG antiglobulin on the platelet surface verifying the disease, but over one third of the patients have no clear identification of antiplatelet antibodies. Bone marrow analysis shows an increased megakaryocytes production as compensatory mechanism to the thrombocytopenia. In this disorder, there is often no splenomegaly and the spleen may be somewhat smaller than typical. Only 2% of patients with ITP have palpable spleens. For this reason, there is virtually no leukopenia or anemia associated with ITP due to hypersplenism. There may be anemia secondary to chronic blood loss. The risk of a fatal hemorrhage in patients with ITP overall is 0.0162 and 0.0389 cases/patient year and predicted 5-year mortality rates are 2.2% for patients <40 years of age and 47.8% for patients older than 60 years.⁵²

The treatment of ITP includes standard measures to treat any ongoing bleeding, medical therapies designed to increase platelet count, and splenectomy. First-line medical therapy options include platelet transfusion, corticosteroids, gamma-immunoglobulin, and the recently approved Rho (d) immunoglobulin.⁵³ Platelet transfusions should be discouraged unless patients are actively bleeding as platelets will become rapidly coated with IgG and will be sequestered and destroyed in the spleen. High-dose corticosteroids produce an initial response in the majority of patients but this is unfortunately not sustained. Approximately 75% of the patients will have an increase in platelet count that is significant within 24 hours of starting high-dose steroids.⁵⁴ However, only 15% to 25% of patients will have a sustained remission with chronic ITP following steroid therapy. A second aspect of initial medical treatment for chronic ITP has been administration of intravenous IgG immunoglobulin. This treatment takes only between 3 and 5 days to show an effect and generally does not put patients into complete remission. The mechanism of action of immune gamma globulin is felt to be saturation of the Fc receptors on the splenic macrophages.⁵⁵ The administered gamma globulin may coat red cells and they may provide a competitive interference such that platelet destruction is decreased. A new available drug is the recently approved Rho (d) immunoglobulin that specifically targets the Fc receptors.

In patients who have not achieved a sustained remission with medical therapy, which is the majority of patient with chronic ITP, an elective splenectomy is recommended. A large series analyzed 135 case series between 1966 and 2004⁵⁶ and reported results in terms of normalization of platelet counts, predictive features evaluating which patients would likely achieve complete response following splenectomy, and reported complications of the procedure including morbidity and mortality (Table 73-8). Among the case series analyzed reporting only on adults (1,731 patients), the complete response upon splenectomy was noted to be 66% (median follow-up of 29 months). Response rates tended to be higher among children, and when cases series evaluating adults and children (2,463 patients) were included in analysis, the complete response rate was noted to be 72% (median follow-up 23 months).⁵⁶ Among cases series that included a multivariate analyses in the systematic review, age (younger) was associated with an increased likelihood of response to splenectomy. Response to prior medical therapy was not found as an independent predictor in those studies, and site of platelet sequestration also was variably reported among the case series evaluated with regard to its predictive role on response to splenectomy. A proportion of patients with initial response to splenectomy (15% to 20%) develops relapse with long-term follow-up. One cause for a failed splenectomy for ITP would be residual splenic tissue most commonly in the form of a missed accessory spleen but also in the form of splenosis.¹⁷ While earlier reports expressed concerns of laparoscopy splenectomy demonstrating a high number of failure rates secondary to residual splenic tissue,⁵⁷ more recent studies suggest similar efficacy of the laparoscopic and open approaches in the management of patients with ITP.⁵⁸

Several new agents have recently been developed or been applied to the treatment of ITP. There were initially several studies with rituximab, which is a chimeric humanized monoclonal antibody directing CD20 against B cells.⁵⁹⁻⁶¹ It was primarily developed to treat lymphoma but it has been used in autoimmune disorders and has been tried in phase 2 studies for chronic splenectomy failure ITP. Response rates have been somewhat sporadic between 25% and 50%. Two new drugs binding the thrombopoietin receptor on megakaryocytes have recently been approved for second-line treatment of chronic ITP: the recombinant peptide romiplostim and eltrombopag, a thrombopoietin nonpeptide mimetic.⁶² Again, it was realized that there is decreased thrombopoietin production for the degree of thrombocytopenia seen in ITP. Romiplostim, which is a fusion protein agonist for thrombopoietin receptor administered by subcutaneous injection, led to response rates of 49% versus 2% for placebo with an overall clinical response rate of 83%.^{48,63} An oral nonpeptide thrombopoietin receptor agonist, eltrombopag, showed response rates of 79% versus 28% in a placebo controlled trial.⁶⁴ Several other newer agents including AKR-501 (thrombopoietin nonpeptide mimetic), and fostamatinib disodium, a spleen tyrosine kinase inhibitor are under clinical investigation.⁶² The role of these and other agents in the armamentaria against treatment of ITP will only likely increase in scope in the future. Future studies will define the role of these new compounds and may decrease the incidence and need for splenectomy.

Thrombotic Thrombocytopenia Purpura

Thrombotic thrombocytopenia purpura, or Moschcowitz syndrome, is a poorly understood much more virulent syndrome than ITP in which thrombocytopenic purpura is only one manifestation. This disease is characterized by widespread occlusion of arterials and capillaries by hyalin membranes that are composed of a combination of platelets and fibrinogen. The classic pentad of symptoms reflects various organ injuries with this microvascular process. This includes thrombocytopenic purpura, with microvascular disease in the skin, neurologic manifestations due to microvascular disease in the central nervous system, renal failure or hematuria due to microvascular disease in the kidney, microvascular hemolytic anemia due to destruction of red cells traveling to damaged small vessels, and fever. The precise etiology is unknown but may be related to an autoimmune response to small vessel endothelial cell antigen.

Table 73-8 Results From 135 Combined Case Series Evaluating Splenectomy for ITP

Cure Rate		
% of patients with normalized platelet counts		
All reports	68.9%	3,506/5,086
Adult series only	66.0%	1,731/2,623
Adult pediatric combined	72.1	1,785/2,468
% of patients with normalized platelet counts	67.2%	779/1,159
With 5-year follow-up		
Complications		
Perioperative mortality		
Total	0.81%	51/6,256
Laparotomy	0.96%	48/4,955
Laparoscopy	0.23%	3/1,301
Perioperative complications		
Total	12.0%	406/3,386
Laparotomy	12.9%	318/2,465
Laparoscopy	9.6%	88/921

Adapted from Kojouri K, Vesely SK, Terrell DR, et al. Splenectomy for adult patients with idiopathic thrombocytopenic purpura: A systematic review to assess long-term platelet count responses, prediction of response, and surgical complications. *Blood* 2004;104(9):2623–2634.

The therapeutic options for this disease include administration of fresh frozen plasma and/or plasmapheresis, high-dose corticosteroids, and antiplatelet drugs.⁶⁵ The benefits seen with plasmapheresis would indicate that there is a toxic substance that is contributing to the etiology of this disorder circulating in the plasma, whereas the benefit of administration of fresh frozen plasma would indicate lack of some necessary substance that has yet to be identified. High-dose corticosteroids also

lead to some benefit. Aspirin and dipyridamole block platelet agglutination. A combination of these therapies now leads to a significant improvement of symptoms in 70% of patients. For patients failing to respond or patients who relapse, a splenectomy has been performed with some success.^{66,67} The majority of the long-term survivors with thrombotic thrombocytopenic purpura (TTP) have undergone splenectomy, implying that this organ has some major role in the pathophysiology of this disease.⁶⁸ The precise mechanism of splenic contribution is unclear. Mortality rates in the past have been as high as 90% to 95% for this disorder but are improving with aggressive treatment plans and a better understanding and diagnosis of this disorder.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia or acquired hemolytic anemia results from antibodies produced to red cell membrane proteins that lead to red cell destruction. This disease is more common in women than in men with the ratio of 2:1, and it typically presents after the age of 50 years. Patients present with acute symptoms consisting of anemia, jaundice, and occasional fever. The spleen is enlarged in approximately half of the patients. Laboratory diagnosis shows a positive direct Coomb test indicating antibody coating the erythrocytes. There is also significant reticulocytosis and increased indirect bilirubin in the serum.

The disease is considered to be either idiopathic in 40% to 50% of the cases in which no identified drug or infectious cause is identified or secondary to infection or drug. Of the secondary cases, the most common infections are mycoplasmal pneumonia, viral infections, infectious mononucleosis, and AIDS, and it can also occur with neoplastic diseases such as leukemia and lymphoma. The major drugs that cause secondary autoimmune hemolytic anemia are penicillin, quinidine, hydralazine, and methyldopa.

A second way that autoimmune hemolytic anemia is categorized is by either cold antibodies or warm antibodies. Warm antibodies are predominantly IgG, whereas cold antibodies are predominantly IgM. This distinction is quite important when considering splenectomy as a treatment. The spleen contains macrophages that bind the Fc portion of IgG. For this reason, in patients with warm antibody hemolytic anemia, the spleen is the primary source of destruction of the red cells by the red pulp macrophages. However, since the spleen does not contain receptors to bind IgM or the cold antibodies, there is no destruction of the red cells in this form of hemolytic anemia. Rather, IgM either causes complement fixation with destruction of red cells in the liver predominantly, or there is agglutination of red cells in peripheral circulation such as the distal extremities leading to peripheral red cell destruction with clinical manifestations similar to Raynaud phenomenon. Splenectomy for patients with cold antibody or IgM hemolytic anemia is not effective.

The treatment of autoimmune hemolytic anemia initially consists of supportive therapy such as blood transfusions. For patients who have disease secondary to an acute infection such as a mycoplasma pneumonia, the disease may be self-limited. For drug-induced hemolytic anemia, the offending agent is removed as quickly as possible. The initial form of treatment is typically high-dose corticosteroids that cause a beneficial response in 75% of the patients. If patients again have drug-induced disease and the offending agent is removed or the acute infection resolves, this may lead to long-term resolution. In idiopathic autoimmune hemolytic anemia, only 25% of patients have sustained remission from steroid use. In patients who have relapse after steroid therapy or who are ineligible for steroid therapy and have warm antibodies, a splenectomy has a high likelihood of benefit. Eighty percent of patients show a good response in correcting the anemia by splenectomy.⁶⁹ This is felt to be almost certainly related to removal of the site of destruction of the erythrocytes but also may be due to a decrease in production of source of antibodies.

Autoimmune Neutropenia (Felty Syndrome)

Approximately 1% of patients with chronic rheumatoid arthritis will develop splenomegaly and neutropenia. This triad of rheumatoid arthritis, neutropenia, and splenomegaly is known as Felty syndrome.⁷⁰ High levels of IgG have been identified on the surface of neutrophils with evidence of increased production of granulocytes in the bone marrow. Pathologic analysis of spleens removed in patients with Felty syndrome show a significant but proportional increase in the white pulp of the spleen as opposed to other conditions of splenomegaly.⁷¹ Microscopically, there is evidence of excess accumulation of neutrophils in both the T cell zone and the white pulp, as well as the cords and sinuses of the red pulp.

Patients with this disease will have recurrent infections due to neutropenia as well as dysfunction of the available neutrophils that are coated with antineutrophil IgG. Recurrent infections, as well as chronic leg ulcers, are the predominant symptoms. Symptomatic patients should undergo splenectomy and the vast majority of patients will have resolution of their neutropenia within 2 to 3 days.⁷² Even

patients who do not have a significant increase in neutrophil count should get some benefit because of improved neutrophil function.⁷³

Hereditary Spherocytosis

Hereditary spherocytosis, also known as congenital hemolytic jaundice or familial hemolytic anemia, is an autosomal dominant disease that is the most common of the congenital hemolytic anemias affecting 1 in 5,000 individuals.⁷⁴ There are a variety of genetic defects in this syndrome that primarily affect spectrin and ankyrin that alter the binding of the cytoskeleton to the erythrocyte cellular membrane causing decreased cellular plasticity with membrane loss.⁷⁵ The normal shape of the erythrocyte is changed from the biconcave disc into a sphere and the decreased membrane-to-volume cell ratio causes a lack of deformability that impacts the passage of erythrocytes through channels of the splenic red pulp. Because of this delay in cell transit, there is ATP deprivation resulting in increased cellular destruction. The condition is more frequent in Caucasians and in African Americans and is usually noted in the childhood or adolescent ages. Since it is an autosomal dominant inheritance, patients may be screened and diagnosed at quite an early age.

The diagnosis is primarily made by evaluation of the red cell smear showing a large number of spherocytes. Spherocytes may also appear during autoimmune hemolytic anemias but in hereditary spherocytosis the Coombs test is negative and an osmotic fragility test may be performed which is diagnostic. Also, contributing to the diagnosis is a positive family history.

Patients with hereditary spherocytosis have mild to moderate anemia, splenomegaly, and jaundice. The patients may have intermittent flares of disease that cause significant increased rates of hemolysis causing jaundice. Between 30% and 60% of patients have been reported to have pigmented gallstones due to the breakdown of hemoglobin.⁷⁴

The treatment for hereditary spherocytosis is splenectomy that is indicated in virtually all patients.⁷⁶ This treatment does not remove the spherocytes but it relieves all symptoms.⁷⁷ The major question involving management of these patients is the timing of splenectomy. Because of the increased incidence of overwhelming postsplenectomy sepsis in very young children, it is usually recommended that patients wait until after the age of at least 4 if not 6 years prior to splenectomy. For younger patients who are very symptomatic and require splenectomy, partial splenectomies have been reported to be beneficial in relieving the abdominal symptoms as well as the anemia and may be a useful alternative procedure until patients reach an age in which total splenectomy is safer.⁷⁸ Patients with partial splenectomies had regrowth of tissue but with short term did not have recurrent anemia.⁶⁹ Patients should be assessed at the time of scheduling a splenectomy for the presence of gallstones and a laparoscopic cholecystectomy should be performed if stones are identified.

Hereditary Elliptocytosis

Hereditary elliptocytosis is a disease that is related to hereditary spherocytosis although not as severe. For patients who are symptomatic, virtually all of the same comments regarding pathophysiology and treatment can be made about hereditary elliptocytosis as for hereditary spherocytosis. This disease is also inherited in an autosomal dominant pattern and the defect is felt to be present in spectrin. The predominant abnormality changes spectrin such that it exists as a dimer instead of tetramer that is the normal structure. This change leads to an alteration in membrane plasticity that creates cells that are more elliptically shaped instead of a biconcave disc.

The signs and symptoms caused in this disease are much more mild than hereditary spherocytosis in that only 10% of patients have clinical manifestations of anemia, splenomegaly, and in some cases jaundice. The treatment recommendation for symptomatic patients is splenectomy again, which may be performed with laparoscopic techniques and also cholecystectomy if gallstones are present.

Hereditary Nonspherocytic Hemolytic Anemia

There is a heterogeneous group of rare hemolytic anemias caused by inherited defects primarily enzymes involved in glycolysis. It is felt that these genetic defects may decrease cellular energy production leading to increased red cell destruction as these cells pass through the relatively hypoxic environment of the red pulp of the spleen. The most common subtypes in this group of hemolytic anemias are pyruvate kinase deficiency and glucose 6-phosphate dehydrogenase (G6PD) deficiency. Patients present with anemia, jaundice, increased reticulocytes, and possibly cholelithiasis. The diagnosis can be facilitated in that the shape of the cell does not show typically spherocytes and there is normal osmotic fragility.

The primary treatment for these diseases is blood transfusion. In G6PD deficiency, splenectomy is not

felt to be beneficial whereas it may reverse some of the symptoms associated with pyruvate kinase deficiency.

Thalassemia

Thalassemia is an autosomal dominant disease with a variety of structural defects in one of the globin chains. The disease is categorized as these are alpha, beta, gamma, or delta thalassemia, depending on which of the globin chains is defective. The vast majority of patients in North America have beta thalassemia. Thalassemia major, otherwise known as Mediterranean anemia or Cooley anemia, is a homozygous expression of this genetic defect. Thalassemia minor is a heterozygous expression and these patients are only mildly symptomatic and are carriers for the more severe form of the disease.

The pathophysiology of thalassemia major or beta thalassemia is the lack of production of normal beta-chain hemoglobin leading to a surplus of alpha-chain hemoglobin in adult patients. These excess globin chains precipitate in the cytoplasm and attach to the inner surfaces of cytoplasmic membrane leading to poor passage of these cells through the splenic sinusoids. This intracellular inclusion then leads to increased destruction and over time causes significant splenomegaly due to this increased clearance of red cells.

The diagnosis is made by identifying microcytic hypochromic anemia with target cells and an increase in reticulocytes on the peripheral smear. Protein electrophoresis will show very low levels of hemoglobin A with predominant amounts of the fetal hemoglobin or hemoglobin F. The clinical symptom of alpha-thalassemia major is severe anemia within the first year of life. Decreased growth rate, enlargement of the head, splenomegaly, and hepatomegaly are the typical clinical findings.⁷⁹

The primary treatment for thalassemia major is frequent transfusions combined with iron chelation therapy. Some patients may develop significant splenomegaly due to overload or hypertrophy from excess trapping of red cells.⁸⁰ Patients may be referred for splenectomy for symptomatic splenomegaly or for patients with massive and frequent transfusion requirements. One report suggested that episodes of transfusion are decreased from 18 per year down to 4 per year after splenectomy. In general, if there are symptoms of massive splenomegaly, these will be resolved with splenectomy as well. As with other hematologic disorders in children, there has been a recent trend toward partial splenectomy particularly in children younger than 4 to 5 years.⁸¹ This will result in symptomatic improvement in between 1 and 2 years with recurrent disease due to hypertrophy of the residual splenic remnant.⁸²

Although splenectomy may be beneficial in terms of the transfusion requirements and local symptoms, the typical mode of death with this disease is myocardial failure due to hemosiderin accumulation. Splenectomy does not alter this cardiac problem to any great extent. In fact, recent data suggest that splenectomy in thalassemia patients increases vascular complications.

Sickle Cell Anemia

Sickle cell anemia is a hereditary hemolytic anemia that is due to a genetic alteration of a single amino acid substitution in the beta chain. This results in a change from glutamic acid to valine in the sixth amino acid position of the beta chain of hemoglobin molecule. Because of this substitution, patients who are homozygous for sickle cell defect have a characteristic stiffening or sickling of the red blood cells when they become hypoxic.⁸³ This change in red cell shape leads to blockage in hypoxic areas such as the red pulp of the spleen. There can occasionally be sequestration crises in which a portion of the blood volume gets actively trapped or sequestered to the spleen during the sickle cell crisis. This pattern of red cell shape change in relatively hypoxic areas can lead to tissue infarction with bone pain, hematuria, abdominal pain, and priapism.

The incidence of this disease, which almost exclusively occurs in the black population, is approximately 0.5% for homozygous disease, with approximately 8% of African Americans being carriers for the sickle cell trait. Patients who have a combination of a sickle cell allele as well as a beta thalassemia allele manifest a similar disease process.

The clinical signs of the disease usually present during the second 6 months of life as in early infancy the patient is asymptomatic due to the presence of fetal hemoglobin. The patients may have acute crises with abdominal pain and bone pain in conjunction with significant anemia. During acute crises of splenic sequestration, there may be massive enlargement of the spleen with an urgent decompressive splenectomy required. Patients who do not need splenectomy for splenic sequestration may be followed as this disease goes through a natural progression of ischemic necrosis of large areas of the spleen with eventual hyposplenism with a shrunken organ by early adolescence. Splenectomy is reserved for the very young patients who have massive splenomegaly in sequestration crises early in life.

Wiskott–Aldrich Syndrome

Wiskott–Aldrich syndrome is an X-linked disease characterized by thrombocytopenia, combined B- and T-cell deficiency, eczema, and a propensity to develop other malignancies. The genetic defect in this disease is felt to be related to an abnormal adhesion molecule affecting immune cell interaction as well as platelet adhesion. Thrombocytopenia is the major problem with this rare disease and most patients present with manifestations of poor clotting, bloody diarrhea, epistaxis, and petechiae at a young age. The platelet counts typically range between 20,000 and 40,000 and the platelets that are present are dysfunctional being small sized, 25% to 50% of normal platelet volume. In this disease, the spleen sequesters platelets and partially degrades them releasing “microplatelets” back into the circulation.⁸⁴

Splenectomy in the Wiskott–Aldrich syndrome was initially avoided as there was a very problematic postoperative course characterized by severe and fatal infections due to the underlying immunodeficiency combined with the potential for overwhelming postsplenectomy infection. However, splenectomy does increase the number, size, and function of platelets and can lead to amelioration of the bleeding problems in very symptomatic patients.⁸⁴ The combination of splenectomy with antibiotic suppression particularly in younger patients may be beneficial. The optimal treatment of Wiskott–Aldrich syndrome is an human leukocyte antigen (HLA) match sibling bone marrow transplantation.⁸⁵ However, splenectomy with antibiotics results in better survival than unmatched bone marrow transplantation. Patients who do not undergo bone marrow transplantation or splenectomy typically do not survive past the age of 5 years. The pathology of spleens removed for Wiskott–Aldrich syndrome shows a near complete depletion of white pulp supporting the clinical immune deficiency seen in this syndrome.⁸⁶

Hypersplenism

7 Hypersplenism is a physical enlargement of the spleen that can be broadly categorized as the neoplastic disorders, hematopoietic disorders of the bone marrow, and metabolic or storage disorders. In neoplastic disorders, the spleen is infiltrative and large typically by leukemic or lymphoma cells. This often happens in the mid or late course of a person’s disease but can be associated with isolated splenomegaly in which the splenectomy is performed not only to treat hypersplenism, but also to make the definitive diagnosis (see Diagnostic Splenectomy section below). Hypersplenism can be associated with diseases of hematopoiesis related to myeloid metaplasia in which the bone marrow is infiltrated with fibrotic material and the spleen becomes a site of secondary non–bone marrow hematopoiesis. Enlargement can lead to symptoms of hypersplenism due to the massive size of the spleen and often the benefits of extramedullary hematopoiesis are outweighed by the sites of circulating blood cell destruction in this enlarged spleen. Secondary hypersplenism can also occur when there is deposition of lipid within the spleen such as in Gaucher disease leading to enlargement that can cause pancytopenia. Each of these categories of secondary hypersplenism is associated with pancytopenia and mass effect of the spleen causing early satiety and weight loss. These disorders typically lead to spleen size more than 1,500 g and can produce spleens that essentially fill the entire left side of the abdomen.

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is the most common of all chronic leukemias. It predominantly affects males more than females with 2:1 predominance and has a peak incidence in the sixth decade of life or older. This indolent disease presents with fatigue, lymphadenopathy, hepatosplenomegaly, and eventually anemia and thrombocytopenia. The disease progression may occur over a 5- to 10-year period.

Figure 73-10. A massively enlarged, 2.2-kg spleen from a patient with chronic lymphocytic leukemia. Superficial areas of infarction are indicated by thin arrows and splenic infarction by the thick arrow.

Patients by definition in stage II or greater CLL will have splenomegaly and anemia and thrombocytopenia secondary to hypersplenism. Splenomegaly often reaches very large sizes and patients may have symptoms secondary to the compressive effects of the large spleen on the stomach with early satiety and pain (Fig. 73-10). Treatment of early stage disease is either observation or treatment with nontoxic doses of alkylating agents such as chlorambucil or cyclophosphamide. There are many treatment options for higher-risk patients, including fludarabine, cyclophosphamide (Cytoxan), rituximab in varied combination, and other chemotherapeutic agents. Many patients will eventually develop hypersplenism and splenomegaly. One strategy that has been employed in particular for patients who are nonoperative candidates is splenic radiation.⁸⁷ The splenic radiation has decreased the size of the spleen improving symptoms due to mass effect, but it may have complications of further thrombocytopenia and leukopenia.

Splenectomy is a highly successful treatment for both the pressure effects due to splenomegaly and the cytopenias.^{88,89} Reports of 85% resolution of thrombocytopenia and 100% resolution of anemia have been published.⁹⁰ The negative feature of splenectomy in this patient population is that they are typically elderly and are typically debilitated from having gone through years of having CLL and potentially prior chemotherapy treatment. In one series in which a prospective comparison was made between splenectomy and fludarabine for later stage CLL, there was a 9% perioperative mortality in the splenectomy group primarily due to sepsis in this patient population.⁹¹ However, in this same study, there were highly significant improvements in thrombocytopenia and anemia. The patients who are younger and have larger spleen sizes tend to do better. In this comparative study of patients with Rai stage IV CLL, the 2-year actuarial survival rate was 51% in the splenectomy arm and a 28% survival rate in the fludarabine arm.⁹¹ At present, splenectomy is recommended for patients who have failed medical therapy and have anemia with transfusion requirements or thrombocytopenia with bleeding or compressive symptoms such as splenomegaly.

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) is a leukemia with the cell of origin, a primitive hematopoietic cell. This primordial cell can differentiate into myeloid cell lines, erythroid cell lines, platelet cell lines, and possibly B lymphoid and T lymphoid cells. CML occurs preferentially in men to women at a 1.5:1 ratio, and like CLL typically occurs in the sixth decade of life or older. This disease varies from CLL in that it invariably progresses from a chronic stage to an accelerated and blastic stage whereas CLL remains more indolent. The initial chronic phase may last anywhere between 1 and 5 years and is characterized by splenomegaly, constitutional symptoms of fatigue, abdominal fullness, and weight loss.⁹² The accelerated phase is apparent with 15% of circulating cells being more immature blast cells and then within 3 to 6 months this generally converts to the terminal blast phase in which the blastic

cells fill the bone marrow and the circulating blood at >30% of leukocytes and may cause destruction of other organs. Death due to infection or bleeding invariably results after the blast crisis begins.

The diagnosis of CML is made by the leukocytosis with myeloid differentiation and presence of granulocytes filling the bone marrow space. Ninety percent of patients have the classic Philadelphia chromosome that is a reciprocal translocation between chromosomes 9 and 22. On the basis of randomized trials, there is no benefit in terms of delaying the accelerated and blast phases of the disease by doing a splenectomy during the chronic phase of the disease. Certain select patients who have significant hypersplenism or splenomegaly may benefit with symptomatic improvement during the chronic phase.^{93,94}

A recent study from MD Anderson reports their experience of splenectomy during the accelerated or blast phase of disease.⁹⁵ Patients were referred for this procedure with symptoms of splenomegaly in 42% of cases, thrombocytopenia in 30% of cases, to potentially improve administration of chemotherapy by reducing the hypersplenism in 19% of cases, and because of symptoms with both hypersplenism and thrombocytopenia in 9% of cases. The perioperative mortality rate in this series of 53 patients was 1.9% with one patient death. There was universal benefit of symptoms related to splenomegaly and there was a marked improvement of platelet count and requirement for platelet transfusions in patients with preoperative thrombocytopenia. The median 6-month transfusion requirements decreased from 21 down to 1, combining both platelet and red cell transfusions. The median postsplenectomy survival was 19 months for patients in the accelerated phase and 6.5 months for patients in the blastic phase of their disease. This report concludes that for select patients who have severe transfusion requirements and/or severe symptoms of splenomegaly, there is objective benefit with relatively low morbidity in patients with this later stage of CML.

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma is the most common cause of lymphoma outnumbering Hodgkin disease by a ratio of almost 6:1 in the United States. Non-Hodgkin lymphoma is a much more heterogeneous disease with a large range of histologic cell types defined by morphology and immunohistochemistry studies to differentiate subgroups of the disease. The clinical course of these different subgroups correlates with these microscopic findings. In general, diffuse or infiltrative non-Hodgkin lymphoma tends to have a worse prognosis than nodular NHL. The diffuse high-grade type occurs most commonly in the younger patient population (age <35 years) or the very elderly. More aggressive non-Hodgkin lymphomas tend to be T-cell lymphomas with the low grade tending to be B cell. Non-Hodgkin lymphoma as opposed to Hodgkin disease occurs at presentation in approximately one-third of cases in extranodal sites while two-thirds are limited to lymphadenopathy.^{96,97} In general, the disease is more diffuse at the time of presentation mandating treatment by combination chemotherapy. It is for this reason that the staging laparotomy classically using Hodgkin disease (see below) is not applicable in NHL.

In patients dying of NHL, up to 80% of patients will have significant splenic involvement with splenomegaly due to lymphatic infiltration.^{98,99} As is true with other infiltrative neoplastic diseases, symptoms of pancytopenia and splenomegaly are common in patients with NHL. Patients who are operative candidates have significant benefit with up to 80% of patients having decreased transfusion requirements and the majority of patients having relief of gastric oppression and pain symptoms due to splenomegaly.¹⁰⁰ In terms of the response of the pancytopenias, it is somewhat dependent on the bone marrow reserve that may have been heavily pretreated with prior chemotherapy and/or radiation therapy. There is no differential test to identify adequate marrow reserve and the only assessment in that situation is whether a patient has a response following splenectomy.

Hairy Cell Leukemia

Hairy cell leukemia is a low-grade lymphoproliferative disorder with characteristic “hairy cells” due to irregular filament projections from the cell surface that give an appearance of hair under light microscopy.¹⁰¹ This leukemia is a B-lymphocyte tumor that infiltrates the bone marrow and spleen with almost no peripheral lymphadenopathy. There may and may not be enlargement of the liver. The disease is much more common in males than in females by a fourfold difference and the onset of disease is typically in the fifth or sixth decade of life.

The initial symptoms most commonly relate to enlargement of the spleen either by direct effects of splenomegaly or by pancytopenia due to hypersplenism (Fig. 73-11).¹⁰² Patients may have early satiety or upper quadrant pain with a large palpable spleen infiltrated with leukemic cells. The enlarged spleen often causes symptoms related to anemia with a transfusion requirement, bleeding due to thrombocytopenia, and frequent infections due to leukopenia. In the past, hairy cell leukemia was

described as the “surgical leukemia” as splenectomy was recommended as the primary treatment since virtually all patients would have resolution of their symptoms of splenomegaly and splenectomy was considered the standard of care.¹⁰³ However, the vast majority of patients relapsed, some as early as 6 to 12 months later, and only 40% to 50% of patients received long-term benefit from the cytopenias due to bone marrow replacement with hairy cell infiltrates.

Figure 73-11. Spleen from a patient with hairy cell leukemia. Note the whitened anterior edge of the spleen and the white “sugar-coating” spots on the surface.

In 1984, medical therapy initially with recombinant alpha-interferon led to improved responses.¹⁰⁴ Newer trials with purine analogs such as pentostatin (2-deoxycoformycin) and 2-chlorodeoxyadenosine provided a beneficial nonsurgical therapy.¹⁰⁵ A randomized trial comparing pentostatin with α -interferon showed a complete response rate of 78% with pentostatin versus 11% with α -interferon and this has now become a first-line therapy.¹⁰⁶ The 10-year survival rate for pentostatin is 96% and 100% for cladribine.¹⁰⁷ Five percent to 10% of patients who are resistant to medical therapy may be offered splenectomy as a salvage therapy.

Myelodysplastic Syndrome

AMM or myelodysplastic syndrome (MDS) with myeloid metaplasia is a poorly understood disorder characterized by a fibrotic replacement of the bone marrow compartment with extramedullary hematopoiesis and massive splenomegaly.¹⁰⁸ The pathophysiology of the disease is poorly understood but includes a nonclonal proliferation of fibroblasts making a dense fibrous stroma that fills the marrow space and contributes to hepatosplenomegaly and lymphadenopathy. This fibrous proliferation may be under control of secreted growth factors such as transformin growth factor beta.¹⁰⁹ Other myeloproliferative diseases include polycythemia vera and essential or idiopathic thrombocytosis.

The clinical symptoms and features of MDS relate to anemia and splenomegaly via direct mass effects or hypersplenism.¹¹⁰ Patients tend to be in the fifth decade of life or older. They present with constitutional symptoms, including weight loss, fatigue, as well as abdominal fullness and discomfort due to splenomegaly. There may be pain from splenic infarctions. Patients may present with bleeding due to thrombocytopenia. Hepatomegaly is present in 50% to 75% of patients and splenomegaly is present in virtually all patients. The massively enlarged spleens in MDS are often some of the largest spleens by weight in most clinical series.

The combination of massive splenomegaly with increased blood flow via the enlarged spleen and hepatomegaly with fibrosis leading to relative portal hypertension creates a unique situation in which some of the clinical symptoms may be similar to portal hypertension from other cause as patients may present with varices and ascites. The diagnosis is made by evaluation of peripheral blood smear that shows immature red blood cells with poikilocytes and tear-shaped cells. There can be either thrombocytopenia or thrombocytosis with platelet counts of greater than one million. Similarly, there may be leukopenia or there may be elevated white blood cell counts similar to CML. Bone marrow biopsy often produces a dry tap due to the fibrotic replacement of the marrows.

Treatment is generally targeted to palliate the symptoms that are present.¹¹⁰ Anemia and thrombocytopenia can be treated with transfusions. There is some role for alkylating agents and steroids, and in patients with thrombocytosis, hydroxyurea is of benefit.¹¹¹ Splenectomy is indicated for relief of significant symptoms of hypersplenism or splenomegaly.¹¹² Hypersplenism is manifested by

anemia and thrombocytopenia with increasing transfusion requirements of bleeding. The patients who have significant pain and early satiety with massively enlarged spleens may benefit by removal of the mass effect. Finally, MDS is a unique situation in which splenectomy may treat portal hypertension as it can increase blood flow through a fibrotic and enlarged liver decreasing variceal bleeding and possibly ascites.¹¹³

The Mayo Clinic has updated the use of splenectomy over the past three decades for patients with myelofibrosis.¹¹⁴ A total of 314 patients have been treated overall with 91 patients treated during the last 10 years. The primary indications for surgery were mechanical symptoms of compression due to massive splenomegaly in 49%, severe anemia in 25%, portal hypertension in 15%, and thrombocytopenia in 11%. Meaningful improvement in symptoms was observed in 30% to 50% of patients, but the overall complication rate was 28% and there were 6.7% perioperative deaths.¹¹⁴ Furthermore, there is no clear impact on overall patient survival or disease course or the intramedullary manifestations of myeloid metaplasia after splenectomy. A recent study of 89 patients from Duke University who underwent splenectomy for myeloid neoplasms similarly demonstrated significant morbidity and mortality rates in this cohort of patients (38% and 18%, respectively), with MDS/myeloproliferative neoplasm, anemia, hypoalbuminemia, and abnormal white blood cell count associated with decreased patient survival rate.¹¹⁵ Given these results, one would have to take into consideration all factors, including severity of symptoms and comorbidities, before recommending splenectomy for this hematologic disorder.

Recent treatment strategies have been employed in MDS in the past 10 years. One is antiangiogenic therapy and the other is immunosuppressive treatment.¹¹⁰ It was recently identified that there was an increase in neovascularity of the bone marrow in patients with MDS and vascular endothelial cell growth factor appears to play a prominent role in pathophysiology. Specific antiangiogenic therapy to block vascular endothelial growth factor (VEGF), including the recently reported trial of thalidomide, led to independence from needing transfusions in a subgroup of patients with MDS. Interest in immunosuppressive therapy in MDS occurred because the subset of these patients with refractory anemia has autoimmune pathophysiology. Young patients or patients with HLA-DR 15 appear to have autoimmune etiology and have responded to immunosuppressive therapy. A new treatment includes JAK2 inhibitors (ruxolitinib); in one study, JAK2 V617F mutation was identified in 63% of patients and independently predicted progression to large splenomegaly.¹¹⁶ Stem cell transplant is considered for appropriately selected patients with primary myelofibrosis deemed to have high-risk disease as predicted by the Dynamic International Prognostic Scoring System-plus or with particular genetic mutational status.¹¹⁷ This scoring system takes into account factors that carry prognostic significance, including age >65 years, leukocyte count >25,000/ μ L, hemoglobin <10 g/dL, circulating blast cells $\geq$ 1%, and presence of constitutional symptoms.¹¹⁸

Metastatic Disease to the Spleen

The incidence of splenic metastases in autopsy studies of patients coming to malignancy ranges between 2.3% and 7.1%.¹¹⁹ It is rare that splenic metastatic lesions are isolated disease. This commonly occurs in colon cancer and ovarian cancer. In patients who have multiple areas of intra-abdominal malignancies, the most common histologies are breast, lung, colorectal, ovarian, and melanoma. There can rarely be isolated metastasis that may be excised for an increase in disease free survival rate particularly for colorectal cancer and melanoma.¹²⁰ Techniques to differentiate benign from malignant processes would include fine needle aspiration biopsy, magnetic resonance imaging (MRI) with gadolinium looking at enhancement patterns, and microbubble control to report using ultrasound techniques.¹²¹

Metabolic or Infiltrative Diseases

Gaucher disease is an autosomal recessive disorder with a deficiency in the lysosomal hydrolase, β -glucosidase, which is encoded by chromosome 1. Gaucher disease is the most common lysosomal storage disease. β -Glucosidase typically degrades sphingolipids like glucocerebroside. There is a marked increased incidence of this disorder in Ashkenazi Jews. There are three types of this disease. Type I, the adult form, comprises 99% of cases and is the one in which splenectomy over the past was useful. The defect in the acid β -glucosidase causes an accumulation of undegraded glycolipids that are taken up by the reticuloendothelial cells and result in infiltration of the spleen, liver, and bone marrow. The most common symptoms with this disease relate to hypersplenism as well as direct effects on massive splenomegaly. Thrombocytopenia with bleeding problems and anemia causing fatigue are the most common effects of hypersplenism. Patients also may have such massive spleens that they have early satiety and weight loss due to gastric compression.

The diagnosis can be confirmed by the measurement of acid β -glucosidase activity in peripheral white blood cells or cultured fibroblasts. With the cloning of the gene, patients can be screened by molecular techniques to identify carriers. Prenatal diagnosis is also available by amniocentesis.

In the past, treatment has included supportive care with platelet transfusions as well as erythrocyte transfusions. Splenectomy was frequently performed for advanced cases and in this disease a significant experience with partial splenectomy was developed in the early 1990s.¹²²⁻¹²⁴ The goals of the subtotal splenectomy are partially to prevent the complications of overwhelming postsplenectomy sepsis and partially to protect the lipid and bone marrow by leaving a residual splenic fragment for continued deposition of lipid. In this disease, the techniques having worked out to safely perform partial splenectomy leaving a small residual upper pole fragment vascularized from the short gastric vessels.

Recently, it has been established that enzyme replacement with purified placental acid β -glucosidase is safe with good efficacy. Patients are given between 30 and 60 units/kg of enzyme intravenously every other week and the symptoms and signs are typically reversed. A recombinant β -glucosidase (alglucerase) is now available for therapy and the role of splenectomy has been largely displaced by this medical management.

INCIDENTAL SPLENECTOMY

In a large series evaluating reasons for splenectomy from the combined series from Barnes Hospital and Brigham & Women's Hospital, the single most common indication (26% of cases) for removing the spleen identified was an incidental procedure.²⁴ This would be categorized as an operation primarily for an adjacent organ or tumor in which the spleen needs to also be removed. The actual primary treatments of those various disease entities in adjacent organs are subjects of multiple other chapters within this textbook, but a few comments should be made regarding the reasons for splenectomy and whether it is always appropriate.

The one common indication for an incidental splenectomy to remove tumors is during removal of the distal pancreas. For decades, the standard procedure when a distal pancreatectomy was performed was a splenectomy. The reason for splenectomy is that the splenic vein is intimately associated with the undersurface of the pancreas and has many direct branches to the pancreatic parenchyma. The splenic artery generally is superior to the pancreatic border and could be preserved but because of removal of the splenic vein and for completeness of the resection, an en bloc resection of the distal pancreas and spleen is typically performed. Because of the interest in splenic preservation due to the incidence of postsplenectomy infection, two different approaches have been employed to remove the distal pancreas without removing the spleen. The more technically challenging operation is a distal pancreatectomy with preservation of the splenic artery and vein. This can be performed only if there is a relatively small amount of invasive tumor or for benign neoplasia in which the splenic vein can be tediously dissected away from the pancreatic tissue tying multiple side branches and then dividing the pancreatic parenchyma leaving the splenic vessel intact. The second spleen preserving distal pancreatectomy involves ligation of the splenic artery and vein but preservation of short gastric vessels and utilizing those vessels as collateral inflow and outflow to maintain splenic viability. A recent report demonstrated no increased risks of preoperative complications or morbidity with this approach.¹²⁵ Removal of the distal pancreas with splenic preservation has also been recently reported as a laparoscopic procedure as well.¹²⁶ For patients with tumors that mandate removal of the lymph nodes of the splenic hilum or with direct association of the tumor with splenic parenchyma, certainly it is more appropriate to do an operation based on neoplastic principles and perform a distal pancreatectomy/splenectomy. In other indications, if the anatomy is appropriate and the completeness of tumor resection is not compromised, splenic preservation is certainly possible.

Additional procedures in which it is quite common to perform a splenectomy include proximal gastric cancers. The importance of complete nodal dissection in terms of long-term results in gastric resections has been debated for several decades. A report from Japan noted that in 20% of proximal gastric cancers there was positive splenic hilum nodes identified as level X lymph nodes.¹²⁷ These authors emphasize the need to perform associated splenectomy with grossly positive nodal disease in the splenic hilum. A long-term retrospective review from Memorial Sloan-Kettering Cancer Center noted that in 23% of gastrectomies in which complete resection of cancer was accomplished, adjacent organs had to be removed, the most common being the spleen.¹²⁸ There was long-term survival in this patient population, but it was emphasized that this aggressive surgery should be employed only when removal of all gross disease is achieved.¹²⁹ A recent randomized study from Korea showed no benefit in doing a

splenectomy if splenic hilum nodes were grossly normal.¹³⁰

Other tumors of the left upper quadrant and retroperitoneum may require splenectomy including large renal cell carcinomas, left adrenal tumors, and retroperitoneal sarcomas that may infiltrate upwards into the spleen. Often the use of splenectomy performed in these situations is to provide adequate exposure to cleanly dissect bulky disease that lies posterior to the spleen. Although the asplenic state does make patients susceptible to infections, the spleen should be viewed as an expendable organ if necessary to accomplish complete resection of malignancies and there should be no hesitation to remove the spleen in those settings to achieve the appropriate complete resection.

IATROGENIC SPLENECTOMY

A poorly reported and uncommonly discussed area of spleen surgery would be removal or preservation of the iatrogenically traumatized spleen during unrelated abdominal operations. Procedures in which there is mobilization of the left upper quadrant with reflection of the spleen and pancreas medially to expose retroperitoneal tissue, such as in left adrenalectomy, and left nephrectomy put the spleen at risk.¹³¹ Simple mobilization of the splenic flexure of the colon can lead to bleeding from the inferior pole of the spleen that may be difficult to control. The ligaments that go directly from the omentum to the capsule of the spleen may be the most common cause of iatrogenic splenic trauma as it is quite a common practice to aggressively retract the omentum as needed for exposure. There are direct branches that are sometimes sizable from the omentum to the splenic capsule, which could result in capsular disruption and troublesome bleeding. A national database on antireflux procedures of 86,411 patients reported an incidence of iatrogenic splenectomy of 2.3%, which translates into 1987 iatrogenic splenectomies for that indication alone.¹³²

Probably the best data for the incidence of iatrogenic splenectomy come from the recently reported series from Vanderbilt, which listed 73 iatrogenic splenectomies over a 10-year period or an average of 7 per year.²⁶ This comprised 8.1% of all splenectomies performed during that time interval. There are probably additional numerous times minor or moderate injuries are inadvertently made to the spleen during unrelated surgeries in which the spleen was not removed but was repaired or salvaged. Just as in trauma to the spleen, the techniques of splenorrhaphy can be employed to preserve the spleen. A recent report indicates that the use of a mesh wrap splenorrhaphy even in the setting of bowel surgery does not lead to an increased incidence of infection.³¹ For minor capsular disruption, the use of the argon beam coagulator for surface cautery is a helpful technique.

Several studies have looked at the incidence and effects of inadvertent splenic injury during colectomy. The Mayo Clinic surveyed 13,897 colectomies and found 59 splenic injuries (0.42%). The majority of these occurred during mobilization of the splenic flexure.¹³³ The 30-day morbidity rate for this subgroup of patients was 34% and, most concerning, the mortality rate was 17%. There were no clear episodes of sepsis. A second large study from the California Cancer Registry of almost 42,000 patients showed that there was a similar rate of inadvertent splenectomy of 0.58%.¹³⁴ Again, this was associated with a distal transverse colon or splenic flexure primary and increased the length of hospital stay by 37.4%. It also increased the probability of perioperative death to 40%. In a large study using the National Inpatient Sample database reviewing 975,825 patients undergoing colectomy between 2006 and 2008, the rate of splenic injury was 0.96%, 84.75% of which cases were treated with total splenectomy, with the majority of remainder being treated by splenorrhaphy (13.6%).¹³⁵ Factors independently associated with splenic injury included, not unexpectedly, transverse, left or total colectomy, but also open operation, malignant tumor, diverticulitis, teaching hospital status, peripheral vascular disease, and emergent admission. Other studies have also found a lower incidence of splenic injury in laparoscopic versus open colonic resections and to what extent this is attributable to technical differences (e.g., better visualization laparoscopically in dissecting the splenic flexure) or to patient selection remains to be defined.

The primary teaching point regarding iatrogenic injuries is that the best way to preserve the spleen is not to damage it in the first place. This requires caution in mobilizing tissue in and around the spleen as well as visual inspection of the attachments of the spleen prior to blunt mobilization. Whenever possible, the spleen should be attempted to be preserved to decrease the risk of postsplenectomy sepsis.

DIAGNOSTIC SPLENECTOMY

One indication for splenectomy is for diagnosis in an otherwise asymptomatic patient. The situation in which splenectomy may be needed to make a diagnosis includes when a dissecting mass lesion is seen within the spleen on CT scan, ultrasound, or MRI scan for which a definitive diagnosis cannot be made radiographically. Another example is when patients have either palpable spleens on physical examination or enlarged spleens by scan and otherwise have no clear diagnostic disorder. [Table 73-9](#) lists the final pathology diagnoses in spleens removed for these two indications over a 10-year period in two major academic medical centers.²⁴ In that series, a total of 122 diagnostic splenectomies were performed, 52 of which were for a splenic mass and 41 for splenomegaly with no other clear diagnosis. An additional 29 were done to further characterize a known hematologic malignancy.

For the patients who have an isolated splenic mass, 60% turned out to be malignant lesions and 40% turned out to be benign lesions ([Table 73-9](#)).²⁴ The majority of the malignant lesions were lymphoma with another large group being metastatic carcinomas including some in which the primary diagnosis had not been made previously. There were two patients with metastatic sarcoma to the spleen. In the benign diagnoses, more than half were cysts and there were also splenic hamartomas and splenic hemangiomas. In a recent series of patients undergoing splenectomy at Memorial Sloan-Kettering Cancer Center for lesions identified on imaging, the incidence of malignancy in the splenectomy specimen was 63% (93 of 148 cases).¹³⁶ The most common malignant pathologies were ovarian cancer, melanoma, and colorectal cancer. Prior history of cancer was the only independent predictor associated with malignant histology in the spleen specimen.

Table 73-9 Final Pathologic Diagnoses in 122 Spleens Removed for Diagnostic Purposes

Total Number of Diagnostic Splenectomies		122
Indication	Diagnosis	
Splenic mass		52
	Lymphomas	17
	Metastatic Cancer	14
	Carcinoma	12
	Sarcoma	2

Adapted from Kraus MD, Fleming MD, Vonderheide RH. The spleen as a diagnostic specimen: A review of 10 years' experience at two tertiary care institutions. *Cancer* 2001;91(11):2001–2009.

In terms of diagnosis of an isolated splenic mass, the majority of these lesions could have been diagnosed by doing a fine needle aspiration biopsy. Certain of these lesions such as the cystic lesions or the hemangiomas would have classic appearance on gadolinium enhanced MRI scan and it is another imaging modality that could be utilized to sort out mass lesions without tissue biopsy. Although there may be some hesitation to do fine needle aspiration biopsies on splenic lesions, due to the risk of bleeding for most mass lesions this would have made the diagnosis and with the exception of splenic hemangiomas essentially all of these lesions could be aspirated without any significant consequence.

The second diagnostic indication for splenectomy is unexplained splenomegaly. In this series over 10 years there were 41 cases, or 4 cases per year at these two hospitals in which a massively enlarged spleen was removed purely for diagnosis.²⁴ The majority of these (58%) turned out to be lymphoma. The remaining 42% were split relatively evenly between benign lymphoid proliferation, benign vascular

lesions, granulomatous disease, as well as splenic infarction and hemorrhage. The role of fine needle aspiration and other percutaneous biopsy for splenomegaly is quite limited as there is considerable risk of bleeding and this form of biopsy would generally be low yield in terms of establishing a diagnosis for this indication.

Another type of diagnostic procedure would be a staging laparotomy for Hodgkin disease. Discussion of this procedure is largely of historical interest as it has limited use in today's current practice in treating this form of lymphoma. A standard practice for pathologic staging between 1960 and 1990 was performance of a staging laparotomy in most patients with Hodgkin disease. The reason to perform this invasive procedure was based on reports that laparotomy altered the clinical stage of disease in approximately 35% of patients and would impact on therapeutic management. Staging laparotomy was typically performed via an upper abdominal midline incision.¹³⁷ This included exploration of the entire abdomen for any abnormal lymph nodes including nodes identified by lymphogram. Even if no abnormalities were found, multiple tissues were removed for pathologic assessment. This included removal of the spleen, bilobar hepatic wedge resections, and bilobar hepatic core biopsies, and multiple lymph nodes samplings.

There are several reasons why the incidence of performing staging laparotomy has decreased over the past 10 to 15 years,¹³⁸ and the primary reason is that it does not alter treatment of Hodgkin disease based on results of recent clinical series. The treatment of patients with stage IB, IIB, IIIB, IVB, IIIA, and IVA Hodgkin disease almost always involves systemic chemotherapy. The only patients who could theoretically benefit from staging laparotomy at present are patients with stage IA or IIA Hodgkin disease who typically may receive treatment with radiation therapy. Even in this subgroup of patients, there is a trend toward not performing staging laparotomy. First, many oncologists use combination chemotherapy even for early-stage disease. Second, for patients who were treated with radiation therapy alone for stage IA and IIA disease, it has been demonstrated in several recent clinical series that ultimate outcome is equivalent whether these patients undergo staging laparotomy or whether they are treated up front with radiation therapy.^{139,140} The reason is that if these patients recur outside of the radiation field during long-term follow-up, they can frequently be salvaged with systemic chemotherapy. Third, performance of staging laparotomy is obviously a major abdominal operation with potential for morbidity and also the reality that treatment of Hodgkin disease will be delayed typically between 4 and 6 weeks. Finally, there are data that patients who survive Hodgkin disease and receive combination chemotherapy are at increased risk for the development of a secondary malignancy that is primarily acute, non-lymphocytic leukemia (ANLL).^{141,142} In some series, the risk of developing ANLL is increased up to 10-fold in patients who have undergone splenectomy as part of their staging work-up for Hodgkin disease compared with patients undergoing similar chemotherapy regimens who did not undergo splenectomy. For all of these reasons, this procedure, which accounted for a large number of the splenectomies performed in major tertiary referral centers and cancer centers, is rarely performed at the present time.

VASCULAR DISORDERS OF THE SPLEEN

Vascular problems with the spleen that can lead to splenectomy include both the venous and arterial problems. The most common situation would be splenic vein thrombosis and splenectomy in this setting is curative for the patient. Splenic artery aneurysms are one of the more common visceral aneurysms and also can be an indication for splenectomy.

Splenic Vein Thrombosis

Splenic vein thrombosis is an unusual cause of upper gastrointestinal hemorrhage that can be cured by splenectomy. The pathophysiology of this disease is an isolated thrombosis of the splenic vein as it travels along the posterior pancreatic body and tail. The splenic venous outflow is then diverted to the short gastric vessels as collateral venous outflow channels. This increased flow via the short gastric veins leads to a high pressure with a dilatation of the submucosal venous plexus primarily in the gastric cardia and fundus with eventual development of gastric varices.¹⁴³

The cause of the splenic vein thrombosis does not involve any pathology of the spleen, but rather typically pathology of the pancreas and possibly the stomach. Pancreatitis or pancreatic pseudocyst is the cause of splenic vein thrombosis in more than 50% of patients in most series. Pancreatic carcinoma with direct invasion and infiltration of the splenic vein is the second most common cause. Other unusual

causes may be a penetrating gastric ulcer posteriorly or retroperitoneal fibrosis.

The diagnosis is made in patients who have upper gastrointestinal bleeding with only gastric varices on endoscopy. Because there is no portal vein hypertension and no cirrhosis of the liver, there are no esophageal varices. The spleen may or may not be enlarged but again there are no other signs and symptoms of cirrhosis. Definitive diagnosis in the past has been made by a celiac angiogram that demonstrates absence of the splenic vein with collateral flow via the gastric veins. Magnetic resonance angiogram/venograms, as well as high-resolution ultrasound, may also make the diagnosis.

Splenectomy is curative as it removes the blood flow via the splenic artery through this organ. This removes all the excess collateral flow, which leads to the venous hypertension and the associated symptoms resolve. Whenever splenic vein thrombosis is diagnosed, even if the patient has not had an episode of bleeding, elective splenectomy should be performed as a prophylactic measure.

Patients with portal hypertension and cirrhosis or partial vein thrombosis have a complex collection of symptoms that include hypersplenism with splenomegaly and thrombocytopenia and anemia. However, the operative risk associated with portal vein hypertension is excessive and splenectomy is virtually never indicated in this setting.

Splenic Artery Aneurysm

Splenic artery aneurysm is uncommon even though it is the second most frequent abdominal artery to undergo aneurysmal changes.¹⁴⁴ Splenic aneurysms occur twice as often in women than in men. Patients can be divided into two distinct groups. First, there are elderly patients whose aneurysms are manifestations of atherosclerosis. Second, young women have apparent congenital predisposition to form splenic artery aneurysms. In these young women, there is an increased risk of rupture of these aneurysms during pregnancy. Inflammatory processes such as pancreatitis may involve the splenic artery and occasionally lead to aneurysm, but more frequently lead to acute bleeding.

Splenic artery aneurysms are typically asymptomatic and may be initially identified as a widened rim of calcification in the left upper quadrant defining the aneurysm boundaries. They may also be discovered as incidental findings on CT scan. If symptomatic, patients experience left upper quadrant pain, nausea, and vomiting. The presence of symptoms suggesting pending aneurysmal rupture and urgent splenectomy with ligation of the splenic arteries is indicated.

When a calcified atherosclerotic splenic artery aneurysm is discovered in a patient older than 60 years with no splenomegaly and no symptoms, surgical excision is not indicated and the aneurysm may be followed to look for signs of enlargement. In younger patients who have a symptomatic aneurysm identified, particularly young women of child-bearing age, an elective splenectomy is recommended to prevent rupture. Nonsurgical approaches include embolization of the splenic artery in patients who are at poor risk for open laparotomy.¹⁴⁴

MISCELLANEOUS INDICATIONS FOR SPLENECTOMY

Splenectomy may be performed infrequently for miscellaneous indications, including splenic cysts, infectious cysts, and splenic abscesses. Also included in the discussion of this category is the frequently described wandering spleen that is a normal spleen that lacks the normal ligamental attachments to keep it in the left upper quadrant. This can present in a variety of ways from an undiagnosed mass to a torsion of the splenic hilum causing acute abdominal pain.

Table 73-10 Primary Neoplasms and Cysts of Spleen

Echinococcal cyst

Cysts of the Spleen

The splenectomy is performed as described earlier often for hematologic malignancies, including multiple forms of leukemias and lymphoma primarily for symptoms of hypersplenism or splenomegaly, or as a staging procedure. Splenectomy for primary neoplasms of the spleen is an infrequent indication. These primary neoplastic processes are listed in [Table 73-10](#).

Hemangioma is most common benign primary neoplasm of the spleen. It is often an incidental finding and may be solitary or multiple. During operation, it can be identified as a more intensely bluish-purple colored lesion when seen from the surface compared to the reddish-purple color of the splenic parenchyma. Hemangiomas can be identified with excellent sensitivity and specificity by MRI characteristics. It is ill-advised to perform a biopsy of a lesion that may be a splenic hemangioma.^{145,146} Hemangiomas of the spleen rarely cause symptoms, but massive hemangiomas either rupture spontaneously or make the spleen more susceptible to a traumatic rupture. In cases of massive hemangioma with capsular distension with pain, either a splenectomy or partial splenectomy may be indicated.

Hemangioendothelioma is a neoplasm that is thought to be slightly more aggressive than the typical benign hemangioma. It is felt to be pathologically an intermediate lesion between benign hemangioma and malignant angiosarcoma. It is not felt to have metastatic potential and generally is an incidental finding. Larger lesions may cause symptoms or be noted for their size and rupture either spontaneously or with minor trauma, all circumstances in which patients with these lesions may undergo splenectomy.

Lymphangiomas also occur in the spleen and are much less common than hemangiomas. They may be multiple or solitary and can be identified by a lighter color and compressibility when seen in surgery.

Two mass lesions that occur in the spleen that are not true neoplasms are hamartomas and inflammatory pseudotumors. Hamartomas are focal development of abnormalities that occur in spleen and other solid organs such as the liver. Hamartomas contain normal cellular elements and are again nonneoplastic but have a random fibrotic organization.¹⁴⁷ The major significance of hamartomas is that they are identified either at laparotomy as incidental findings or they are seen as incidental lesions on CT scans done for other reasons.¹⁴⁸ Inflammatory pseudotumors are described throughout most organs and have also been described in the spleen. These sometimes are quite large with a wide variety of reactive cells. A subcategory of inflammatory pseudotumors of the spleen is related to mycobacterial infection, particularly in HIV-positive patients. There have been reports of primary splenic pregnancy that is considered the rarest site of ectopic pregnancies.

Figure 73-12. The visceral surface of a spleen with a true congenital splenic cyst.

Cysts of the spleen are relatively common lesions seen across all age groups, may be multifocal, and are not typically of parasitic origin. The diagnosis of splenic cysts can be ascertained by ultrasound or CT scan. These benign lesions have no clinical significance unless they reach a large size. As discussed earlier in the history of splenic surgery, the first reported case of a successful elective splenectomy was done for a splenic cyst. This was an enormous cyst at the tip of the spleen and was felt to be likely an ovarian mass and found to be arising from the spleen at laparotomy ([Fig. 73-12](#)). Today there would be a tendency to do a cyst enucleation or partial splenectomy for peripheral cystic lesions that are large and symptomatic. An alternative approach is unroofing the cyst and leaving a portion of the cyst wall in place and this can frequently be done laparoscopically.¹⁴⁹

The only parasitic cyst involving the spleen is from *Echinococcus granulosus* or a hydatid cyst. The incidence of echinococcal cyst in the spleen compared to the liver is a ratio of approximately 30:1.

However, the spleen is the third most common site of echinococcal cysts behind the liver and lung.¹⁵⁰ Diagnosis should be suspected in patients in areas such as New Zealand, Australia, and parts of the Western United States where echinococcal disease is common. The complement fixation test is the most reliable serologic study for this organism. The treatment of echinococcal cysts is splenectomy. As with echinococcal cysts of the liver, it is of utmost importance not to rupture the cyst and expose the patient to the scoleces. For large and peripheral cysts in which risk of rupture is high, the contents of the cyst should be carefully aspirated and replaced with hypertonic saline.¹⁵¹ In a recent report from Greece, surgeons preserved 8 out of 19 spleens with echinococcal cysts by doing partial splenectomy.¹⁵⁰

Abscess of the Spleen

Splenic abscess is uncommon but is an important disease because it is associated with a significant mortality rate and may be cured by splenectomy.¹⁵² In most series, the mortality rate ranges between 40% and 100%.¹⁵³ The typical patient has hematogenous seeding of the spleen by bacteria from a remote source such as endocarditis or from intravenous drug abuse.¹⁵⁴ There may be in some cases direct spread of infection from adjacent intra-abdominal sources. Finally, splenic trauma treated conservatively may eventually result in an infected splenic hematoma. In 80% of the cases, there is an additional source of infection in locations other than the spleen, and in only 20% of cases is the splenic abscess the sole source of sepsis identified. Enteric organisms account for two-thirds of the splenic abscesses and staphylococcus and streptococcus comprise the remainder of the cases.

Patients typically present with signs and symptoms of sepsis including fever, malaise, and leukocytosis. When the spleen is the sole site of infection, patients will have significant left upper quadrant tenderness and guarding. Abdominal x-ray films may show gas in the spleen and an ultrasound or CT scan with contrast will be diagnostic to show an abscess with reactive rim.

The treatment of choice for patients who can undergo a laparotomy and have the splenic abscess as an isolated or prominent component of septic syndrome is splenectomy. If the spleen is the only source of infection, removal of the spleen should be curative and result in the recovery of the patient. If patients have multiple sites of infection or are too sick to undergo laparotomy, percutaneous drainage of splenic abscesses may be attempted but this is not successful because of frequent spillage and assimilation of bacteria in the left upper quadrant of the abdomen.

Ectopic Spleen (Wandering Spleen)

Ectopic spleens, or the so-called wandering spleens, occur because of either extreme laxity or absence of the normal ligaments that attach the spleen to the left upper quadrant. This allows the spleen to essentially drop to the lower abdomen in either the right lower quadrant or left lower quadrant by the force of gravity attached by its vascular pedicle.¹⁵⁵ This condition of a wandering spleen occurs 13 times more frequently in women than in men. The wandering spleen presents most commonly in adults but can cause symptoms in children. The diagnosis may be made by palpable lower abdominal mass confirmed by a CT scan or a nuclear imaging spleen scan to be splenic tissue. The ectopic spleen creates symptoms typically when there is torsion of the pedicle causing acute ischemia and acute pain. The treatment for a wandering spleen as an incidental finding at laparotomy or if the torsion can be corrected and the spleen appears to be viable is to do a splenopexy tacking it to its native position in the left upper quadrant. If the spleen appears infarcted, then a splenectomy must be performed.¹⁵⁶ The wandering spleen is ideally suited for laparoscopic splenectomy as it is generally free from ligaments or attachments and other organs.¹⁵⁷

SPLENECTOMY: OPERATIVE TECHNIQUE

The choices of operations available currently to approach the spleen in an elective manner are open splenectomy, laparoscopic splenectomy, or partial splenectomy. [Table 73-11](#) lists indications for splenectomy and whether a partial splenectomy is indicated. Certain principles apply to all patients undergoing elective splenectomy. First, all patients should receive appropriate preoperative vaccination with Pneumovax (pneumococcal polyvalent vaccine) and possibly also vaccination against *Haemophilus influenzae* and *Neisserian meningococcus* 10 to 14 days prior to the procedure if possible. Patients must have appropriate blood products ready as often patients are anemic and thrombocytopenic due to hypersplenism as described earlier.

Table 73-11 Operative Indications for Splenectomy and If Total or Partial Splenectomy Is Indicated

Disease	Need for Splenectomy	Partial Splenectomy
Hereditary spherocytosis	Always	Yes
Hereditary elliptocytosis	Sometimes	Yes
Thalassemia	Sometimes	Yes
Sickle cell anemia	Rarely	No
Wiskott–Aldrich syndrome	Sometimes	No
Autoimmune hemolytic anemia	Usually	No
Autoimmune neutropenia	Sometimes	No
Immune thrombocytopenia purpura	Usually	No
Thrombotic thrombocytopenia purpura	Sometimes	No
Hairy cell leukemia	Rarely ^a	No
Chronic lymphocytic leukemia	Sometimes	No
Chronic myelogenous leukemia	Sometimes	No
Non-Hodgkin lymphoma	Sometimes	No
Angiogenic myeloid metaplasia	Sometimes	Yes
Mastocytosis	Rarely	No
Gaucher disease	Rarely ^a	Yes
Hodgkin disease	Rarely ^b	No
Splenic vein thrombosis	Always	No
Splenic abscess	Usually	No
Splenic cyst	Rarely	Yes
Echinococcal cyst	Always	No

^aSplenectomy rarely indicated in current practice because of effective medical therapy.

^bSplenectomy rarely indicated because of change in current therapy.

Figure 73-13. Lateral mobilization permits the spleen to reach the surface of a midline wound despite the presence of intact hilar vessels.

The operative technique for open splenectomy involves either a midline abdominal incision or a left subcostal incision. For patients with massive splenomegaly defined as >1,500 g in adults and >1,000 g in children, a long midline incision should be employed.¹⁵⁸ The components of the splenectomy include division of the avascular lateral and posterior attachments to mobilize the spleen (splenophrenic, splenorenal, and splenocolic ligaments), ligation of the short gastric vessels separating the upper half of the spleen from the greater curvature of the stomach, and ligation of splenic hilar vessels in a controlled manner to avoid injury to the pancreatic tail. Although one approach particularly for small spleens that are mobile is to initially divide the lateral attachments and place packs in the left upper quadrant to elevate the spleen and then proceed with the vascular dissection (Fig. 73-13), this should be discouraged particularly in patients who are thrombocytopenic or patients with massive splenomegaly. In this situation, splenectomy should start by obtaining vascular control before manipulating the spleen, which can lead to capsular rupture and significant blood loss.

The preferred operative approach in patients with splenomegaly¹⁵⁹ and hypersplenism would be to first divide the attachments of the left lateral segment of the liver and retract this to the right side of

the abdomen exposing the greater curvature of the stomach. Then, starting at the mid portion of the greater curvature of the stomach, the branches of the left gastroepiploic artery and vein including short gastric vessels are ligated sequentially, completely dissociating the stomach from the superior portion of the spleen (Fig. 73-14). Through this window into the lesser sac created by dissecting the short gastric vessels, the splenic artery can be identified at variable locations along the superior border of the pancreas. A loop of this tortuous artery at its most superior or cranial portion is safest as at those points it is farthest away from the splenic vein as well as away from pancreatic parenchyma. The artery may be simply ligated once or twice with heavy silk ties at that location and does not need to be divided. By dividing short gastric arteries as well as ligating the main splenic artery, the vast majority if not all of blood flow into the spleen is controlled before manipulating the spleen to mobilize it. If capsular disruption occurs, the amount of blood loss thus is greatly minimized. Following vascular control, the lateral and posterior attachments are divided and the spleen is elevated to near the level of the abdominal wall musculature ventrally. The splenic hilum can then be dissected tying vessels in a controlled manner. Upon completion of splenectomy, the use of drains in the surgical bed is not routinely indicated unless there is concern for or confirmed pancreatic injury.

Figure 73-14. Technique for elective splenectomy. A: The inferior pole is reflected laterally by the assistant's fingers, exposing the

lower edge of the hilar peritoneal envelope. **B:** The hilar peritoneum is opened, here shown progressing from inferior to superior. **C:** Individual vessels are identified and suture is ligated.

For patients with ITP, platelets should not be given until the spleen is either removed or at least until the arterial inflow is controlled because of clearance of transfused platelets by the spleen in this disease. Similarly, for this disease as well as other diseases in which the spleen is the site of platelet or blood cell destruction, it is important to identify and remove accessory spleens. The majority of the accessory spleens occur in the splenic hilum and they can also occur in the omentum, along the superior border of the pancreas, in the bowel mesentery, and in the pelvis in some situations. The incidence of accessory spleens and open splenectomy ranges between 15% and 30%.

Partial splenectomy can be performed on the basis of the segmental blood supply to the spleen. The spleen is mobilized with good visualization. The inferior segmental arteries are generally ligated and the artery and veins are ligated as a predemarkation of blood flow to the spleen. The splenic parenchyma is then transected and the cut to the surface can be controlled using materials that induce coagulation or the argon beam coagulator.^{160,161}

In the past 5 to 10 years, the standard practice for an elective splenectomy in many large centers has become a laparoscopic approach.^{23,162,163} Even patients with massive splenomegaly are frequently now being approached with a laparoscopic splenectomy with the use of a hand port.¹⁶³ In one series, there were no conversions in 49 patients with splenomegaly defined as splenic length >17 cm or spleen weight >600 g, although in 12 patients with splenic length >22 cm, a hand-assisted approach was used.¹⁶⁴ Another series noted a higher incidence of conversion to an open procedure when the spleen weighed more than 2,000 g.¹⁶⁵

The technique of laparoscopic splenectomy can either be typically performed with patients in the supine position with a roll under their hips to prop that portion of the abdomen up approximately 30 degrees or it can be done with the patient in the lateral decubitus approach. Typically one 12-mm port and two or three 5-mm ports (depending upon the size of the spleen) are positioned below the costal margin from the subxiphoid area to the anterior axillary line (and laterally off the tip of the 11th rib for the additional port in cases of larger spleens). The omental, inferior attachments and the short gastric vessels are divided with a harmonic scalpel device. It has been reported that careful exposure of the splenic hilum with the direct ligation of the vessels is a much safer technique than the laparoscopic equivalent of a trauma splenectomy in which the hilum is stapled without precise vessel dissection.¹⁶⁶ Once the vessels are ligated, the spleen is placed into a large plastic bag and brought to the port and this allows careful morselization of the spleen without having to enlarge the incision and without fracture and spillage elsewhere in the abdomen. The laparoscopic approach has been successfully applied for cases of massive splenomegaly¹⁶⁷ and partial splenectomy.¹⁶⁸ In some cases, the use of a handport can facilitate safe removal of the spleen, particularly when very enlarged. In one study, there was no difference in morbidity between patients receiving conventional laparoscopic resection and those facilitated by a hand port, although the length of hospital stay and duration of surgery were longer in the latter group, likely attributable to the fact that those patients tended to be older, have larger spleens, and carry a malignant diagnosis.¹⁶⁹ More recently, the single incision/single-port laparoscopic surgery approach has also been successfully applied for splenectomy but remains a technically more demanding approach with less well-defined benefits over conventional laparoscopy.¹⁷⁰ Similarly, robotic-assisted splenectomy has been reported with successful outcomes and low conversion rates, but its benefit over conventional laparoscopy remains to be defined.¹⁷¹

Laparoscopic splenectomy has also been reported for removal of the wandering spleen.¹⁵⁷ In this indication, it is actually a much easier operation as the spleen is free and the hilum is very easily exposed. The removal of accessory spleens can be done laparoscopically as well and reports indicate that adding a hand port for palpation can assist in this type of procedure.¹⁷² In one study, laparoscopy was found to be more sensitive than CT scan for identification of accessory spleens.¹⁷³

A recent new technique has been added to treatment of splenic disorders that is radiofrequency ablation.^{174,175} Radiofrequency ablation was developed in the mid-1990s primarily to treat liver lesions. There are a variety of commercial products that essentially destroy tissue indiscriminately by heating to 100°C. The largest experience is with either primary or metastatic tumors in the liver but this has also been utilized in treatment of bone metastasis, kidney lesions, lung lesions, and breast cancer. Recent reports indicate that radiofrequency ablation probes can be used successfully as a minimally invasive technique to treat splenic disorders such as thalassemia. There also may be a role for radiofrequency ablation in terms of treating trauma to the spleen as a way to control severe injuries

hemostatically.^{175,176}

Sequelae of Splenectomy and Hyposplenism

Splenectomy can have an impact on immune function and coagulative state in patients. The impact of splenectomy in immune function is most importantly manifested by the phenomenon of overwhelming postsplenectomy sepsis.^{177,178} This was initially recognized as an important epidemiologic phenomenon in the early 1950s and multiple studies of splenectomized patients define key features of this increased susceptibility to infection. It is clear that the risk of postsplenectomy sepsis is inversely related to age.¹⁷⁹ The younger the child is the more impact and greater risk of developing overwhelming postsplenectomy sepsis.¹⁸⁰ This feature has clinical implications as elective splenectomies are not performed for patients with hereditary erythrocyte syndromes until after the ages of 6 to 10 years. In adults, there is still anywhere between a 40% to 60% increased risk of sepsis compared with patients with normal splenic function. These postsplenectomy septic episodes typically occur within the first 2 years of splenectomy in 80% of the cases. In adults, the reason for the splenectomy also relates to the incidence of sepsis. In trauma, the instance of sepsis in a large series was 1.4% whereas in thalassemia the incidence was 24.8%. Patients with any associated immunodeficiency such as malignancies or patients undergoing chemotherapy for treatment of Hodgkin disease are also at increased risk for sepsis. The mortality rate of postsplenectomy sepsis is between 50% and 60% in most series.

8 The types of organisms that account for infection are typically encapsulated organisms. These bacteria may have special features that allow them to be opsonized and cleared from a circulation by the spleen making them more dangerous in hyposplenic or splenectomized patients. The most common organism causing postsplenectomy sepsis is *Streptococcus pneumoniae*, which accounts for 50% of septic episodes in most series. In decreasing order of frequency, other bacteria associated with postsplenectomy sepsis are *Hemophilus influenza*, *Neisseria meningitidis*, β -hemolytic streptococcus, *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas* species.¹⁷⁹ The current recommendations for patients who are having elective splenectomy would be to vaccinate susceptible individuals to pneumococcus strains (Table 73-12).¹⁷⁹ This is ideally done 2 weeks before the operation if possible, but should be done at any time preoperatively or even postoperatively if the patient was not vaccinated. Recent studies have shown that administration of vaccine with the first postoperative visit does not lead to beneficial immune stimulation. Waiting for 14 days postoperatively is equivalent to waiting 1 month or longer.¹⁸¹ Therefore, vaccination starting at 2 weeks after an unplanned splenectomy is ideal timing. There are choices of polyvalent vaccines including pneumovax 23 and Pnu-Immune 23, both of which provide protection against virtually all common strains of pneumococcus.¹⁸¹ For patients who are at particularly high risk because they may be immunosuppressed, there are also polyvalent vaccines against *Neisseria meningitides* and *Haemophilus influenzae* type B. Patients younger than 2 years and patients receiving chemotherapy for malignant disease may not be able to generate an immune response to vaccines and should be vaccinated either after the age of 2 years or when not receiving chemotherapy, respectively. Finally, because of the risk of very rapid progression of sepsis in a postsplenectomy state, patients who have had splenectomy for any reason should be given a Medic-Alert bracelet.

Table 73-12 Guidelines for Prevention of Postsplenic Sepsis

Vaccinate with polyvalent pneumococcal vaccine at least 10–14 days prior to splenectomy if possible
If splenectomy is urgent wait, until at least 14 days postprocedure to vaccinate
For high-risk patients (immunosuppressed, children <10 years of age), meningococcal vaccine and haemophilus influenzae vaccine
Antibiotic prophylaxis for children <5 years of age
Early antibiotic treatment for initial signs of infection
Medic-Alert bracelet

Two recent studies highlight the incidence of increased relative risk and the number of infections after splenectomy. The relative risk for infection within 90 days of a splenectomy was 10.2% compared with 0.6% in the general population. In patients undergoing appendectomy for acute appendicitis a control group undergoing an abdominal procedure, there was still increased risk of infection in splenectomy of 10.2% compared with patients who had appendectomy of 4.2%.¹⁸² The relative risk of

postsplenectomy infection decreased over time with an overall hazard ratio of 4.6-fold between 90 days and 365 days after splenectomy and 2.5-fold for more than 365 days after splenectomy.¹⁸² There is definite evidence of that use of vaccination decreases this risk of infection. Another large national study from Scotland showed that the overall rate of first severe infection was 7.0 per 100 person-years after splenectomy. In that subgroup of patients who had a severe infection, the rate of subsequent infections was significantly increased and the second severe infection rate was 44.9 per 100 person-years and a third episode of severe infection was 109.3 per 100 person-years.¹⁸³ This would indicate that the patients who had significant postsplenectomy sepsis should be observed very closely and counseled on seeking medical attention for any sign of any infectious process. There are also accumulating data with the increased trend particularly in blunt splenic trauma and other hematologic diseases for spleen-preserving procedures such as splenorrhaphy or partial splenectomy, that there are still increased risks of infection in these patients that are comparable with those of patients who have a complete splenectomy.¹⁸⁴

A recent survey of practicing surgeons indicated patterns of utilization of immunization for splenectomy patients. Of the practices, essentially universally 99.2% of active surgeons said they do immunize patients they treat with splenectomy.¹⁸⁵ Virtually every one administers vaccine to pneumococcus. Most (72.4%) practicing surgeons routinely use a *Haemophilus influenzae* type vaccine, 62.8% give meningococcal vaccination, and 56.7% utilize all three vaccines. A small portion of practicing surgeons immunize their patients who have splenorrhaphy (15.7%) and a very small proportion immunize patients who have splenic injury but who are managed nonoperatively. Current guidelines would be that all patients with elective splenectomies should have prophylactic immunization prior to surgery whereas patients who have unexpected splenectomy should have immunization on or after 14 days after the procedure. All patients should get pneumococcal vaccines and patients at high risk should have vaccination for *H. influenzae* and meningococcus.^{185,186} Revaccinations may be considered at appropriate time intervals, taking into account the age and immune status of the patient, although these are not typically needed for *H. influenzae*.

For decades, it has been known that patients after splenectomy are susceptible to infections as described earlier. It has only recently been realized that there are a variety of vascular complications that occur to a greater degree in patients with splenectomy than in cohort of abdominal surgery patients without splenectomy.¹⁸⁷ These include arterial thrombosis, venous thrombosis, and pulmonary artery hypertension. Data from patients with hereditary spherocytosis who have undergone splenectomy report between a 5.6- and 7.2-fold increase in ischemic heart disease compared with patients who do not have splenectomy. The most marked finding for arterial events occurs in thalassemia in which patients who undergo splenectomy have a 20-fold increase in arterial atherosclerosis of arterial structures. Acute portal venous thrombosis is reported after splenectomy in one series up to 4.8% for a variety of patients.¹⁸⁸ It is clearly seen more commonly after splenectomy in patients with cirrhosis and hypersplenism where the rate of portal vein thrombosis (PVT) may be 30% to 40%.¹⁸⁹ A recent study suggests that splenic volume may predict the likelihood of patients with cirrhosis developing PVT, with spleen volumes >450 mL associated with significantly increased risk for PVT.¹⁹⁰ Prophylactic anticoagulation may be considered in these high-risk patients.¹⁹¹ Moreover, while some earlier study data suggested a higher incidence of PVT in patients undergoing laparoscopic surgery when postoperative imaging is routinely performed,¹⁹² there does not appear to be a clear association between the surgical approach (laparoscopy vs. open) of splenectomy and the incidence of clinically apparent PVT, despite concerns of pneumoperitoneum and perhaps more commonly longer splenic vein stump length in laparoscopic cases leading to a more thrombotic state in the portal venous system. In one recent study of 162 splenectomised patients, the incidence of PVT was 1 of 60 (1.7%) in open splenectomy patients and 3 of 102 (2.9%) in laparoscopic splenectomy patients.¹⁹³ The incidence of venous thrombosis may go beyond the mesenteric/portal venous system and include deep venous thrombosis in the pelvis and lower extremities as well as subsequent pulmonary embolus to a much greater extent. This also has led to increased evidence of pulmonary arterial hypertension in patients after splenectomy for hematologic diseases. A large retrospective analysis of 375,748 patients undergoing abdominal surgery found patients undergoing splenectomy to be at highest risk for venous thromboembolic events.¹⁹⁴

The pathogenesis of these vascular events after splenectomy is likely multifactorial.¹⁸⁷ They may involve some elements of hypocoagulable state due to altered platelet function and number. There may be some disturbances in vascular epithelium related to the other blood elements that are altered after splenectomy. The spleen moreover may also play an important role in clearing certain cellular

microparticles that may have a prothrombotic effect, such as phosphatidyl-serine.¹⁹⁵ There is also evidence that there may be some changes in lipid profiles after splenectomy that would promote atherosclerosis and thrombosis.¹⁸⁷ Although these vascular events clearly are increased in frequency, they nonetheless occur in a minority of patients but would argue toward using splenectomy conservatively particularly in certain high-risk individuals such as patients with thalassemia.

Finally, splenectomy may increase the risk of development of certain malignancies. In one recent study of 8149 cancer-free American veterans who had undergone splenectomy with long-term follow-up, there was an increase noted in various both solid and hematologic malignancies, many of these occurring years following surgery.²⁵ Other studies have shown less consistent associations of splenectomy with subsequent malignancy; one Danish and one Swedish study found an increased incidence of malignancy among patients undergoing splenectomy only for nontrauma-related etiologies.^{142,196} Further study is needed to define the precise association between splenectomy and subsequent malignancy.

SECTION K: SURGICAL ENDOCRINOLOGY

Chapter 74

Breast Disease

Thanh U. Barbie and William E. Gillanders

Key Points

- 1 Any clinically suspicious mass, even in the absence of an imaging abnormality, needs to be biopsied as up to 15% of breast cancers are mammographically occult.
 - 2 Core needle biopsy is the preferred strategy for breast cancer diagnosis. Core needle biopsy is less invasive and less expensive than excisional biopsy and facilitates definitive breast cancer treatment planning.
 - 3 The upgrade of lobular neoplasias diagnosed on core biopsy at time of surgical excision to malignancy is 1% to 3% and as such surgical excisional biopsy is no longer indicated.
 - 4 All expert groups in North America agree that screening mammography should be performed in women 50 years of age and older. However, differences exist about whether screening should be performed between ages 40 and 49.
 - 5 Surgical options for the treatment of DCIS include breast-conserving surgery as a component of breast conservation therapy (partial mastectomy and postoperative radiation therapy) or simple mastectomy.
 - 6 Sentinel lymph node biopsy has replaced axillary lymph node dissection for axillary staging, and the therapeutic impact of axillary lymph node dissection may be limited to specific subsets of breast cancer patients.
 - 7 Local regional management of invasive breast cancer consists of breast conservation therapy (partial mastectomy with radiation therapy) or mastectomy, noting that the choice in locoregional management does not typically impact the recommendation for adjuvant medical therapy.
 - 8 Among patients undergoing partial mastectomy, performing cavity shaving halved the rates of positive margins and reexcision.
 - 9 A negative surgical margin for invasive breast cancer is now defined as no tumor at the ink margin. Given the potential for gaps between lesions in DCIS, a negative surgical margin is still defined as ≥ 2 mm, understanding that this practice may evolve pending more study results.
 - 10 Nipple sparing mastectomy is a safe option for BRCA mutation carriers, with no local regional recurrences at up to 37 months of follow up.
 - 11 Axillary radiation therapy may result in less morbidity than axillary lymph node dissection in patients with early stage breast cancer with clinically negative axillary examinations who have ≤ 2 positive sentinel lymph nodes.
-

ANATOMY

Surgical Anatomy of the Breast

The boundaries of the mature adult breast are the second rib superiorly, the sixth rib inferiorly, the sternal edge medially, and the midaxillary line laterally. Breast tissue also extends into the axilla. Posteriorly, the breast lies on top of portions of the deep investing fasciae of the pectoralis major muscle, the serratus anterior muscle, the external abdominal oblique muscles, and the upper extent of the rectus sheath (Fig. 74-1). The breast is composed of skin, subcutaneous tissue, and breast parenchyma. The skin overlying the breast is thin and contains hair follicles, sebaceous glands, and exocrine sweat glands. The subcutaneous tissue is composed of fat, vasculature supplying the skin, lymphatics, and nerves. The breast parenchyma consists of parenchymal components and stroma.

Breast tissue is located within the superficial fascia of the anterior thoracic wall and consists of 15 to 20 lobes of glandular tissue that are divided by connective tissue with adipose tissue filling the space

between the lobes (Fig. 74-2). Each lobe is composed of 20 to 40 lobules, which are themselves composed of 10 to 100 alveoli. Each lobe ends in a lactiferous duct that dilates into lactiferous sinuses, which then open through constricted orifices into the nipple. The suspensory ligaments of Cooper are fibrous connective bands that extend from the deep fascia to connect to the dermis, providing the breast with both support and mobility. There is significant variation in breast size with the average nonlactating breast weighing between 150 and 225 g, whereas the lactating breast may exceed 500 g.¹ The left breast is commonly slightly larger than the right.² The upper outer quadrant of the breast contains more breast parenchyma and is the most frequent site of both benign and malignant breast diseases.

The skin of the nipple and the areola is highly pigmented and somewhat wrinkled, composed of stratified squamous epithelium. Deep to the nipple and the areola are bundles of smooth muscle fibers that are arranged radially, circumferentially, and longitudinally, allowing for erection of the nipple from stimuli. Along the margin of the areola are sebaceous glands and sweat glands. Accessory glands known as Montgomery glands have nodular elevations (tubercles of Morgagni) that open onto the surface of the areola. The nipple and the areola are highly innervated, with the nipple containing numerous free sensory nerve endings and Meissner's corpuscles, whereas the areola contains both Ruffini-like endings and Krause-end bulbs.³ The sensory innervation of the breast is mainly the lateral and anterior cutaneous branches of the second through sixth intercostal nerves. There is also a small region of skin over the upper portion of the breast that is supplied by the anterior or medial branches of the supraclavicular nerve that arises from the cervical plexus.

The arterial blood supply to the breast consists of the internal mammary artery (perforating branches), the posterior intercostal artery (lateral branches), and several branches of the axillary artery including the superior thoracic artery, the lateral thoracic artery, and the pectoral branches of the thoracoacromial artery. The breast's venous system parallels its arterial system, consisting of the internal mammary veins, the posterior intercostal veins, and the axillary vein tributaries.⁴

Figure 74-1. The adult female breast. The upper and medial portions of the breast rest on the pectoralis major muscle, and the inferolateral portion rests on the serratus anterior.

Lymphatic Drainage

The lymphatic flow from the breast is unidirectional through thin-walled, valveless vessels that are interconnected through three groups. The primary group of lymphatic vessels comes from within the gland in the interlobular spaces and along the lactiferous ducts. The lymphatic vessels that drain the skin, nipple/areola, and the central portion of the gland constitute the subareolar plexus. The third plexus is on the deep surface of the breast and communicates with small vessels in the deep fascia underlying the breast. More than 75% of the lymph from the breast passes to the axillary lymph nodes, whereas the remainder passes to parasternal nodes. The flow of lymph to either the axillary or the parasternal nodes is independent of the quadrant from where the lymph originated.⁵ Occasionally, lymph flow can be found outside of these three interconnected plexuses, occurring along the lateral cutaneous branches of the posterior intercostal arteries, within the rectus sheath or subperitoneal plexus by following branches of the intercostal and musculophrenic vessels, or directly to subclavicular or apical nodes.⁶

Figure 74-2. The breast consists of 15 to 20 lobes of glandular tissue. Within each lobe, the lobules are composed of branched tubuloalveolar glands. Each lobule ends in a lactiferous duct. These ducts dilate into lactiferous sinuses beneath the nipple.

Figure 74-3. The axillary lymph nodes are divided into three levels by the pectoralis minor muscle. The level I nodes are inferior and lateral to the pectoralis minor, the level II nodes are below the axillary vein and behind the pectoralis minor, and the level III nodes are medial to the muscle against the chest wall.

The axilla is a pyramidal compartment between the upper extremity and the thoracic walls, which can be thought of as consisting of four walls, an apex, and a base. The anterior wall consists of the pectoralis major/minor and its associated fasciae. The subscapularis muscle, teres major muscle, latissimus dorsi muscle, and associated tendons form the posterior wall. The medial wall consists of the serratus anterior muscle and associated intercostal muscles of the upper four or five ribs. A thin strip of the humerus and the bicipital groove, which is between the insertion of the muscles of the anterior and posterior walls, forms the lateral wall. The apex is an aperture that extends into the posterior triangle of the neck through the cervicoaxillary canal, which is bounded by the clavicle anteriorly, the scapula posteriorly, and the first rib medially. The base of the axilla is the axillary fascia and the skin.⁶

The axillary lymph nodes have traditionally been divided into three levels, corresponding to their location relative to the pectoralis minor (Fig. 74-3). Level 1 nodes (external mammary, axillary vein, and scapular lymph node groups) are inferior and lateral to the pectoralis minor; level 2 nodes (central

lymph node and some subclavicular lymph node groups) are behind the pectoralis minor; and level 3 nodes (subclavicular lymph node group) are medial to the pectoralis minor. The interpectoral nodes (Rotter nodes) are located between the pectoralis major and minor muscles along the lateral pectoral nerve. The supraclavicular nodes are contiguous with the apex of the axilla. The internal mammary nodes are located in the first six intercostal spaces within 3 cm of the edge of the sternum, with the highest concentration of nodes found in the first three intercostal spaces.^{7,8}

I		Stage I: Prepubertal
II		Stage II: Breast bud stage with elevation of breast and papilla; enlargement of areola
III		Stage III: Further enlargement of breast and areola; no separation of their contour
IV		Stage IV: Areola and papilla form a secondary mound above level of breast
V		Stage V: Mature stage with projection of papilla only and is related to recession of the areola

Figure 74-4. Tanner stages of breast development.

BREAST PHYSIOLOGY

Breast Development

As epidermal appendages, mammary glands likely evolved from ancient apocrine glands that were associated with hair follicles.⁹ The mammary gland is a complex secretory organ consisting of multiple different cell types. Epithelial cells form the ductal network of the gland, which is embedded within a fat pad composed of adipocytes. In addition, there are vascular endothelial cells that make up the blood vessels, stromal cells including fibroblasts, and immune cells. During the three stages of mammary development (embryonic, pubertal, and pregnancy/lactation), these cells undergo an intricate series of changes under the regulation of hormones and regulatory factors, resulting in permanent changes to the mammary gland that both modify its architecture and biologic characteristics.¹⁰ Understanding breast development and morphology is extremely important to the study of both premalignant and malignant conditions.

In humans, mammary gland development starts in the sixth week of fetal life with the formation of bilateral milk lines or ectodermal thickenings that extend from the axilla to the groin. These ridges rapidly regress except for those of the thorax, where invagination of ectoderm cells into the mesenchyme results in mammary bud formation. In the human embryo, at about 5 months, the deep layer of the mammary bud epithelium starts to proliferate and produces about 10 to 25 secondary buds, which will later correspond to lactiferous ducts. Canalization, or the formation of lumens within the solid core of these epithelial structures, occurs later in development. By birth, six to eight of these ducts are patent and empty into the nipple.¹¹⁻¹⁵ A parallel bundle of an additional 25 smaller ducts also appear and are the precursors to the milk-producing units of the breast.¹⁶ The subareolar lymphatic plexus also develops from the ectoderm in a similar fashion,¹⁷ while the nipple forms from the proliferation of the mesenchyme under the areola.¹⁴

In infants, only small ductal structures are seen within the stroma and during childhood, these structures continue to grow isometrically at a rate similar to the rest of the body until puberty.¹⁸ These initial stages of breast development are not dependent on sex steroids but are likely governed by numerous growth factors that regulate the epithelial-mesenchymal interaction, including Lef-1,¹⁹ parathyroid hormone-related protein, and the type 1 parathyroid hormone/parathyroid hormone-related protein receptor.²⁰

During puberty, the female glands enlarge rapidly secondary to maturation of the ductal system into a

lobuloalveolar system. This is characterized by thickening of the ductal epithelium, elongating ducts, and an increasing amount of periductal connective tissue. In addition, stem cells at the tips of the ductal tree form terminal end buds, which are highly proliferative and give rise to alveolar buds. In early puberty, these alveolar buds empty into a terminal ductal lobular unit and are referred to as lobules type 1. Under the influence of ovarian hormones (estrogen and progesterone), lobules type 1 will differentiate into lobules type 2, which are characterized by smaller but more numerous buds that are noted as ductules or alveoli. It has been postulated that each menstrual cycle fosters new budding that never fully returns to the baseline of the prior cycle.^{21,22} In addition to estrogen and progesterone, pubertal breast development is also dependent on other hormones and regulatory factors including prolactin, growth hormone, glucocorticoids, growth factors (hepatocyte growth factor, IGF-1, IGF-2, FGF, neuregulins especially heregulin), vitamin D receptor, metalloproteinases, and PTEN.^{23–28}

As these developmental events are occurring, physical changes in the breast contour and the appearance of the nipple become evident and are illustrated as the five Tanner stages of breast development (Fig. 74-4).²⁹

Menstrual Cycle

During a 28-day menstrual cycle, the mammary gland undergoes five histologic phases described by Vogel: proliferative (days 3 to 7), follicular phase of differentiation (days 8 to 14), luteal phase of differentiation (days 15 to 20), secretory (days 21 to 27), and then menstrual (days 28 to 2). The first phase starts with the proliferation of the mammary epithelium and is characterized by mitotic figures, a predominant eosinophilic cell type, dense stroma, and tight lumen. During the follicular phase, the epithelial cells start to differentiate with the appearance of multiple cellular types (luminal columnar basophilic, intermediate pale cells, and basal clear cells with hyperchromatic nucleus or myoepithelial cells). In the luteal phase, the prior dense stroma starts to loosen and the lumen starts to open with secretions. Also, the basal clear cells have prominent vacuolization, consistent with the known effects of progesterone on the glycogen content of cultured endometrial epithelium.³⁰ The secretory phase is notable for active apocrine secretion from luminal cells and an edematous stroma. During the menstrual phase, the stroma returns to a dense and cellular form, the lumen distends with secretions, and the basal cells have extensive vacuolization.³¹ These five phases depict the morphologic changes that occur in the breast from normal ovarian hormone cycling during menses, further supporting the notion that the mammary gland is not a resting gland but one that is dynamic.

Pregnancy and Lactation

Although the pubertal phase is marked by significant lobular development, the mammary gland does not achieve full differentiation until after pregnancy and lactation. In early pregnancy, the distal ducts continue to proliferate, resulting in more lobules and more alveoli within each lobule. However, by midpregnancy, proliferation of the lobules ceases and instead alveolar cells begin to differentiate into acini by hypertrophy and the ability to secrete colostrum into the lumina of the ductules. By the third trimester, the acini become distended with colostrum and the breast's connective tissue and fat become largely replaced by glandular proliferation. In addition, the connective tissue becomes infiltrated with plasma cells, lymphocytes, and eosinophils. There is also a marked increase in vascularity. The stage of lactogenesis or the ability to synthesize and secrete milk marks the final stage of maturation of the mammary gland (lobule type 4).^{32,33} Following lactation or during weaning, the mammary gland involutes with lobules type 4 returning to the prepregnancy state as lobules type 2 and 3.^{34,35}

The hormones and regulatory factors that govern mammary development during pregnancy and lactation overlap with those previously discussed for pubertal breast development, with estrogen, progesterone, and prolactin playing chief roles. Other hormones and regulatory factors include intracellular signaling molecules (c-erbB, hox genes, cell-cell adhesion molecules such as E-cadherin, cell cycle protein cyclin D1, RANK-L, slug transcription factor), activins and inhibins including STAT5, hypothalamic peptides, thyrotropic-releasing hormone, and lactogenic hormones.^{36–43}

Menopause

By menopause, the mammary gland is mainly replaced by fat as the glandular epithelium undergoes apoptosis. As such, the postmenopausal phase is characterized by a decrease in lobules and ducts.^{44,45}

In summary, human breast development is a progressive process that is initiated during embryonic life, with glandular maturation starting at puberty, and attainment of full breast differentiation only with subsequent pregnancy and lactation.

CLINICAL EVALUATION OF THE PATIENT WITH BREAST DISEASE

Breast disease is an extremely common clinical problem. Most women who present to a breast health specialist will have benign breast disease. One of the primary goals of the evaluation is to determine whether the breast problem represents benign or malignant breast disease. With benign conditions, the goals are to reassure the patient and if indicated, provide symptomatic treatment. With a malignant condition, prompt evaluation and treatment should be undertaken, typically involving a multidisciplinary team including a breast surgeon, medical oncologist, and radiation oncologist. In this section, the tools that a clinician uses to evaluate patients with breast disease are discussed including the history, clinical breast examination (CBE), diagnostic imaging studies, and biopsy procedures.

DIAGNOSIS

Table 74-1 Medical History of a Breast Problem

General
Age at menarche
Number of pregnancies
Number of live births
Age at first birth
Family history of ovarian cancer, gynecologic cancers, and other cancers, including affected relative, age of onset, and presence of bilateral disease
History of breast biopsies (and histologic diagnosis, if available)
<u>Premenopausal women</u>
Date of last menstrual period
Length and regularity of cycles
Use of oral contraceptives
<u>Postmenopausal women</u>
Date of menopause
Use of hormone replacement therapy
Specific
Onset
Duration
Frequency
Severity
Relationship to menstrual cycle or use of hormone replacement therapy

As the first step in the evaluation of a breast problem, it is important to elicit a relevant history. This includes the specific history related to the presenting breast problem, as well as a more general history focused on assessing breast cancer risk. This includes age at menarche, number of pregnancies, number of live births, and age at first live birth. Family history and history of breast biopsy should also be elicited. Menopausal status (for premenopausal patients, the time in their menstrual cycle) and the use of any hormonal therapies should be assessed ([Table 74-1](#)).

Clinical Breast Examination

CBE is performed in both the sitting and supine positions ([Fig. 74-5](#)). The patient is disrobed from the waist up and then provided a front-opening gown. Visual inspection is first accomplished with the patient sitting upright with the arms relaxed to her side. The bilateral breasts are compared for size and shape. It is normal to find slight differences in breast size, with the left breast often slightly bigger than the right. Breast shape is also contrasted. Recent changes to breast size or alterations in breast shape can be concerning signs and need to be evaluated by the provider, as tumors located superficially can cause changes to the breast contour. The skin of the breasts is inspected for dimpling, edema (peau d'orange), and/or erythema. In cases of significant erythema and peau d'orange, the provider needs to consider the diagnosis of an inflammatory breast cancer (IBC) versus an infectious etiology. This is followed by close inspection of the nipples for symmetry. Although some women have a lifelong history of nipple inversion, any new history of nipple inversion needs to be regarded with a high index of suspicion. Next, the nipple–areola complex is evaluated for any eczematous changes or ulcerations (to suggest conditions such as Paget disease of the breast [PDB]). The patient is then asked to raise her arms to

allow for a more complete visual inspection of the lower aspect of the breasts bilaterally. The visual examination is completed when the patient is asked to place her hands on the hips and then to contract the pectoral muscles. This allows for a final visual assessment of breast symmetry. Furthermore, tumors deep within the substance of the breast involving Cooper's ligaments can result in skin retraction and can sometimes be seen best with contraction of the pectoral muscles.

Figure 74-5. Breast examination. **A:** The patient's ipsilateral arm is supported by the examiner to relax the pectoral muscle while the axillary nodes are examined. **B:** Bimanual examination of the breast in the upright position. **C:** Bimanual examination in the supine position with the arm raised over the head.

With the patient remaining in the sitting position but now with the pectoral muscles relaxed, palpation of the regional lymph nodes of the neck, clavicles (infraclavicular and supraclavicular), and axilla is then performed. To best delineate the axillary lymph nodes, the patient should be examined with the ipsilateral arm supported. Attention is paid to evaluate the size, consistency (soft or firm), and characteristics (mobile or matted, tender or nontender) of the lymph nodes. Bimanual palpation of the breasts for masses and asymmetry completes the sitting examination.

The patient is then placed in the supine position with the ipsilateral arm raised above the head and the contralateral breast covered with the gown. The breast tissue is carefully palpated to evaluate for masses and asymmetry. It must be noted that generalized lumpiness is not a pathologic finding, with most normal breasts having more nodularity in the upper outer quadrants, at the inframammary ridge, and in the subareolar region. Comparing the breasts for symmetry by palpation may help discriminate benign findings from those that require additional evaluation. The area examined extends from the clavicle to the lower rib cage and medially from the sternal border to the midaxillary line. In addition, the axillary tail of the breast should be carefully palpated. The three search patterns that have been described are concentric circles, radial spoke method, and the vertical strip pattern (Fig. 74-6). As the first two methods can result in a less than thorough examination of the nipple–areola complex, we prefer the vertical strip pattern as it incorporates this area. Otherwise, with the other two search patterns, a separate examination of the nipple–areola complex needs to be performed.

Diagnostic Mammography and Breast Ultrasound

1A woman who has an indeterminate or abnormal CBE will typically benefit from a diagnostic imaging evaluation, which can include targeted ultrasound, mammography, and/or MRI. It is important to note

that any clinically suspicious mass, even in the absence of an imaging abnormality, needs to be biopsied as up to 15% of breast cancers are mammographically occult.⁴⁶

Soft tissue densities and clustered microcalcifications are two common mammographic findings suggestive of breast cancer. Soft tissue densities can appear as well-defined round/oval/lobulated masses, spiculated masses, irregular masses, or as areas of architectural distortion without an obvious mass (Fig. 74-7). Nearly 90% of spiculated soft tissue masses are associated with invasive cancer whereas well-defined solid masses are rarely predictive of malignancy. Microcalcifications can have benign or malignant features, with benign calcifications often appearing rim-like, large, coarse, smooth, round, and/or oval in appearance. Calcifications that are associated with malignancy tend to be smaller in size, ranging between 0.1 and 1 mm in diameter. They are typically clustered, numbering 4 to 5/cm³. Histologically, these represent intraductal calcifications in areas of necrotic tumor or calcifications within mucin-secreting tumors. In addition, malignant microcalcifications can often appear in a granular or linear branching pattern, with the linear branching pattern being highly associated with malignancy (Fig. 74-8).

Figure 74-6. Clinical breast examination search patterns: vertical strip, radial spoke, and concentric circles.

Figure 74-7. Mammographic masses. A: Spiculated mass with calcifications. B: Lobulated mass with indistinct posterior margin. C: Well-circumscribed mass.

Breast ultrasound is another important diagnostic imaging modality for the evaluation of breast masses and/or mammographic abnormalities. Breast ultrasound is complementary to mammography

and is particularly valuable for the evaluation of breast masses. Breast ultrasound can increase the sensitivity and specificity of mammography for detection of breast cancer.⁴⁷ Ultrasound can differentiate a cystic mass from a solid one, characterize a palpable lesion that is not seen on mammography, and can assist with determining the actual size of a lesion. Ultrasonographic features that are used to characterize a lesion include shape (oval, round, lobular, irregular); margin (circumscribed, obscured, microlobulated, ill-defined, speculated); orientation (parallel or not parallel to skin); matrix echogenicity (anechoic, hypoechoic, hyperechoic); homogeneity (homogeneous, heterogeneous); and attenuation (indifferent, shadowing, enhancement).

Figure 74-8. Microcalcifications. The branching, irregular appearance is classic for ductal carcinoma in situ.

Figure 74-9. Comparison of core needle biopsy specimen (A) and fineneedle aspiration specimen (B). Only the core specimen can demonstrate the architectural detail.

Diagnostic MRI

Gadolinium contrast-enhanced MRI is complementary to mammography and breast ultrasound. It is not typically used for the evaluation of benign breast masses but does have a high sensitivity for detection of breast cancer. As such, MRI is most commonly used to evaluate extent of disease and exclude occult breast cancers in patients with newly diagnosed breast cancer. In a meta-analysis of 44 studies, the sensitivity and specificity of diagnostic breast MRI was determined to be 90% and 72%, respectively.⁴⁸ The role of MRI in the evaluation of patients with newly diagnosed breast cancer is discussed in the section on Evaluation of the Patient with Breast Cancer.

Biopsy Procedures

Breast biopsy is one of the most common general surgery procedures performed in the United States. There are multiple different types of breast biopsy ranging from fine needle aspiration (FNA) biopsy to excisional biopsy. The different types of breast biopsy are discussed later.

Fine Needle Aspiration

FNA of the breast is the least invasive breast biopsy procedure. FNA can be used for both diagnosis and treatment and can be performed using palpation or image guidance. During FNA cells or fluids are removed from the breast using a small gauge needle (20 to 25 gauge). FNA is commonly used to sample suspicious breast and axillary lesions especially those that are palpable. Other indications include drainage of simple cysts and small abscesses. The patient is placed in the supine position on the examination table at a 30-degree angle with the arm of the involved side above the head. When lesions are lateral or in the axilla, the patient is positioned in the lateral decubitus position. Inframammary lesions may require an assistant to help retract the breast. For ultrasound guidance, the probe is positioned directly over the area of interest. As an example, for a breast cyst, the probe would be placed directly over the cyst with the cyst located at the side of the probe; this way the shortest distance to the cyst is shown. Prior to aspiration, the cyst is thoroughly scanned in all planes for septa or loculations to facilitate complete aspiration. The skin is then prepped with an antiseptic solution and further scanning is performed in a sterile fashion. With the nondominant hand steadying the cyst, 1 to 2 mL of 1% lidocaine is injected into the skin. A 20-gauge needle with a 5 or 10 mL syringe is inserted in a plane parallel to the chest wall directly toward the center of the cyst. The plunger is then slowly retracted to create a vacuum to aspirate the cyst contents. For palpable lesions not requiring ultrasound guidance, aspiration can be performed in a similar fashion. The aspiration site can be dressed with an adhesive bandage. If there is bleeding, pressure is applied for 15 minutes. Other potential complications include infection and failure to adequately sample the area of concern. In institutions with experienced cytopathologists, diagnostic FNA has a reported sensitivity of 98% and a specificity of 97%.⁴⁹ However, as the tissue architecture cannot be evaluated by FNA, the diagnosis of invasive cancer cannot be made. In the past, FNA was commonly used to sample palpable breast masses as part of the Triple Test for evaluation of palpable masses. Currently, ultrasound can more accurately assess these lesions and low suspicion lesions are followed with serial imaging. High suspicion lesions are best sampled by core needle biopsy to allow assessment of tissue architecture (Fig. 74-9).

Core Needle Biopsy

2 Core needle biopsy is also a minimally invasive strategy for breast biopsy. Given the limitations of FNA, core needle biopsy allows for more tissue to be sampled, permitting a histologic diagnosis, and offering the ability to discriminate between invasive and noninvasive breast cancer. Core needle biopsy can be performed by palpation, but ultrasound-guided core needle biopsy typically offers superior results. Ultrasound imaging and patient preparation are similar to that described for patients undergoing FNA. The skin and planned needle tract are anesthetized with lidocaine, and a small stab incision is made with a No. 11 blade prior to needle entry. A common core biopsy device consists of a hollow 14-gauge needle (range: 18-gauge to 11-gauge) with a spring firing mechanism. More advanced devices have vacuum assistance and an automated firing mechanism. Under ultrasound guidance, the tip of the needle is guided toward the lesion, often to its edge as the needle excursion is typically approximately 2 cm. Advancing the needle beyond the abnormality can result in sampling error and/or injury to the chest wall. The device is then fired and the needle is withdrawn, with the resultant “tissue core” placed into formalin. Three tissue cores are obtained to ensure adequate sampling of the abnormality. A clip is then deployed under ultrasound guidance to mark the biopsy site for future reference. For palpable masses, the procedure can be performed without ultrasound guidance. The nondominant hand is used to steady the mass and is positioned perpendicular to the entry point of the needle device to avoid inadvertent needle stick injury.

For nonpalpable lesions that cannot be imaged by ultrasound but are present on mammography (most commonly microcalcifications), stereotactic core biopsy can be performed. Stereotactic techniques use the principle of triangulation, which allows the precise location of a breast lesion to be determined in three dimensions.⁵⁰ The patient can be upright or prone depending on the machine. More commonly, the patient is placed in the prone position on the stereotactic table, which has an opening for the breast. A mammography unit is attached beneath the table and compresses the dependent breast. An initial scout image is obtained perpendicular to the compressed breast and evaluated. The skin overlying the

area of interest is then prepped and anesthetized with lidocaine injected in the skin and along the planned needle path. Using a No. 11 blade, a small stab incision is made. The needle is then advanced through the skin puncture site and toward the center of the lesion on the basis of the computed calculations. The needle is advanced to the leading edge of the lesion and its position is verified by imaging. Following biopsy, repeat images are obtained to ensure that the area of concern has been adequately biopsied. The procedure may be repeated to obtain additional cores. Most stereotactic core biopsies are performed with vacuum assistance allowing for greater accuracy. If suspicious microcalcifications are biopsied, the samples can be examined with specimen imaging to ensure the presence of microcalcifications within the biopsy samples. At the completion of the procedure, manual compression is used to obtain hemostasis, and the skin nick is closed with adhesive strips with a transparent medical dressing. An ice pack and compression dressing can also be used.

Failure to obtain an adequate sample can result in a false-negative test result, although the false-negative rate is very low. In some instances, the results of the core biopsy may not be definitive and a surgical excision is required. If the core biopsy demonstrates a concerning lesion, surgical biopsy is required to exclude a diagnosis of malignancy. In the clinical context of persistent suspicious physical examination or imaging abnormalities (discordance between clinical and/or imaging findings and pathology results), surgical excision is required. Please see [Table 74-2](#) for indications for surgical excision after core biopsy.

Incisional Biopsy

Incisional biopsy typically involves surgical removal of part of a large mass for diagnosis. With the advent of core needle biopsy techniques, incisional biopsy is rarely required. However, if a core needle biopsy is nondiagnostic and the mass is too large to remove without significant cosmetic compromise, an incisional biopsy can be performed for definitive diagnosis.

INDICATIONS/CONTRAINDICATIONS

Table 74-2 Indications for Surgical Biopsy After Core Biopsy

Atypical ductal hyperplasia
Radial scar
Columnar cell hyperplasia with atypia
Papillary lesions
Lack of concordance between appearance of mammographic lesion and histologic diagnosis
Nondiagnostic specimen (including absence of calcifications on specimen radiograph when biopsy is performed for calcifications)

Excisional Biopsy

Excisional biopsy of the breast is the surgical removal of a breast lesion. Although core needle biopsy has largely obviated the need for excisional biopsy for diagnostic considerations, indications for this procedure still remain. Indications include breast lesions that are presumed to be benign but require excision, discordance between clinical evaluation/diagnostic imaging and pathology requiring further tissue sampling, high-risk lesions (including atypical ductal hyperplasia, radial scar, and papilloma) identified on core biopsy, abnormalities that are close to the nipple or chest wall, small breasts that are not amenable to core biopsy (given the needle excursion is often 2 cm), and for patients who cannot tolerate stereotactic core needle biopsy. In addition, excisional biopsy may be considered for complex cysts, aspirated cysts that do not completely resolve, and when follow-up imaging for a lesion with previous benign pathology from a core biopsy shows an increase in size or has suspicious changes. Excisional biopsies may also be performed for likely benign lesions that are greater than 2 cm, painful, or recurring, or where the mass represents growing cysts or fibroadenomas. Patient preference for complete removal of a benign lesion may also be an indication for excisional biopsy.

For nonpalpable lesions, the abnormality can be localized preoperatively using a needle localization wire that is placed with the patient in a sitting position with the breast compressed by a labeled grid plate. Various needles used include the Kopans needle (check mark wire), the Hawkins needle (multiple barbs and the only retractable wire for repositioning), and the Homer needle (J wire and nontransectable needle). For lesions that are superficial and can be readily imaged by ultrasound, needle

localization can be performed under ultrasound guidance. The patient is then taken to the operative setting, where excision of the lesion can be performed under local anesthesia with sedation or general anesthesia. In the operating room, the patient is placed in the supine position with the arm ipsilateral to the index lesion positioned at 90 degrees. Appropriate padding of the arm and wrists should be undertaken. The operative site is then prepped and draped in a sterile fashion. Intraoperative localization is performed by evaluating the imaging studies and palpating the needle (for nonpalpable lesions) or by direct palpation. For lesions located in the upper half of the breast, transverse or curvilinear incisions are made along Langer's lines. If an incision is needed in the lower half of the breast, radial incisions are used. When possible, periareolar or inframammary incisions are made as they result in the best cosmesis. Prior to incision, a local anesthetic is injected into the skin and along the path of the needle localization wire. The incision is then typically made directly above the palpable mass or the tip of the needle (Fig. 74-10). Alternatively, an incision can be made next to the needle and then followed down to its tip to find the target lesion. Once the skin incision is made, the thickest possible flaps, which would still result in fully removing the lesion anteriorly, are developed. The specimen is then excised with electrocautery. The specimen is oriented with sutures, with the short stitch designating the superior margin and the long stitch designating the lateral margin. Palpation of the cavity is performed to ensure complete removal of the lesion. Specimen imaging is performed to confirm excision of the lesion of interest. The skin is closed in two layers. Cyanoacrylate tissue adhesive is then applied, allowing the patient to take a shower within 24 hours. For allergies to skin glue, adhesive strips can be applied. No pressure dressing is needed. A sports bra may be worn to stabilize the breast for the first 48 hours.

Skin Punch Biopsy

For any suspicious cutaneous lesion of the breast or chest wall, a biopsy can be obtained using a punch biopsy device, which consists of a circular blade. Punch biopsy devices are available in various sizes ranging from 1 mm to 8 mm, with the 2-mm and 4-mm size most commonly used in breast biopsies. The area to be biopsied is first selected. Common sites are the most abnormal-appearing site within a lesion or the edge of an actively growing lesion. The involved skin is cleansed and infiltrated with 2 to 3 mL of 1% lidocaine. The punch device is held vertically over the skin and rotated downward using a twirling motion until the subcutaneous fat or the hub of the device is reached. The specimen is then transected at the base with iris scissors. The skin is approximated with an interrupted stitch or U-stitch.

Figure 74-10. Incision placement for needle localization biopsy. **A:** The mammogram demonstrates that the lesion (arrow) is inferior to the point of wire entry. **B:** Incision placement inferior to wire entry to allow access to the lesion.

COMMON CLINICAL PROBLEMS AND MANAGEMENT ALGORITHMS

The most common clinical breast problems include breast masses, breast pain, nipple discharge, and breast infections. Clinical algorithms for the evaluation of these common breast problems have been developed to facilitate optimal care.

Breast Mass

A breast mass is defined as a palpable area in the breast that may be either benign or malignant. When a woman presents with a palpable breast finding, a thorough history and physical examination needs to be performed. The history should include a thorough review of the patient’s medical problems and any risk factors associated with breast cancer (see the section on Management of Patients at High Risk for Breast Cancer).

In women younger than 35 years with no family history of premenopausal breast cancer or other risk factors, a targeted ultrasound is an appropriate initial imaging approach for a breast mass that appears clinically benign (Algorithm 74-1). The ultrasound is used to determine whether a dominant mass is present, as normal glandular tissue of the breast, especially in young women, may feel nodular. In a review of 605 women younger than 40 years who were referred for evaluation of a breast mass, only 36% of the masses detected by patients had a surgical correlate. Furthermore, only 29% of the masses detected by primary care providers were confirmed.⁵¹ Consideration can then be made regarding the need for additional imaging such as mammography or an MRI. In women aged 35 years or older, the initial imaging approach to a palpable mass should include mammography and ultrasound. These studies should be obtained prior to any biopsies are performed as postbiopsy changes can distort subsequent imaging evaluation. Of note, all clinically suspicious palpable masses need to be biopsied even in the absence of imaging findings as 15% of breast cancers can be mammographically occult (Algorithm 74-2).⁴⁶ Ultrasound also provides important information about the etiology of a breast mass and can further categorize the mass as either cystic or solid. Workup of a cystic lesion typically involves aspiration of the cyst, with further evaluation based on the results of the aspiration (Algorithm 74-3). The definitive diagnosis of a breast mass is often confirmed by a core needle biopsy, although FNA is an appropriate alternative (Table 74-3). Core needle biopsy is typically preferred to excisional biopsy.

TREATMENT

Table 74-3 Management of Breast Masses Based on Core Biopsy Diagnosis

FNA Diagnosis	Treatment
Malignant	Definitive therapy
Suspicious	Surgical biopsy
Atypia	Surgical biopsy
Benign	Possible observation ^a
Nondiagnostic	Surgical biopsy

^aSee discussion in text on clinical approach to the patient with a solid breast mass.

Algorithm 74-1. Diagnosis and management of the patient with a clinically benign breast mass. The use of imaging studies varies according to age because breast carcinoma is infrequent in women younger than 35 years old.

Algorithm 74-2. Diagnosis and management of the patient with a clinically indeterminate or suspicious solid breast mass. In this circumstance, imaging studies are insufficient to exclude malignancy, and tissue sampling is required.¹

Algorithm 74-3. Diagnosis and management of the patient with a cystic lesion. Bloody fluid on aspiration, failure of the mass to resolve completely, and prompt refilling of the same cyst are indications for surgical biopsy.

Breast cysts are common causes of dominant masses in premenopausal and perimenopausal women. If a cyst is found in a postmenopausal woman in the absence of hormone therapy use, it should be regarded with a high degree of suspicion. Palpable masses that present as benign solid masses include fibroadenomas, fibrocystic disease, and fat necrosis. Fibrocystic breast disease has been used to describe a variety of benign breast disorders associated with nodular breast tissue. This term, however, should be reserved for women who have a biopsy consistent with one of the histologic components of fibrocystic change. Breast surgery, blunt trauma, injection of native or foreign substance such as fat and silicone, and radiation therapy can result in fat necrosis. On clinical examination and mammographic imaging, fat necrosis can mimic a malignancy, often leading to a biopsy. However, when oil cysts, which are circumscribed masses of mixed soft tissue density and fat with a calcified rim, are present radiographically, a definitive diagnosis of fat necrosis can be made (Fig. 74-11). See the section on Benign Breast Disease.

Breast Pain

Breast pain (mastalgia, mastodynia, idiopathic breast pain) is a common concern and is rarely (0.5% to 3.3%) representative of a breast cancer. It is noted that some IBCs can present with pain. While two-thirds of patients present with cyclical breast pain, another one-third has pain that is unrelated to the menstrual cycle and more likely to be secondary to a breast or chest wall lesion.⁵²

Cyclical breast pain is associated with hormonal changes during the menstrual cycle and often occurs the week prior to the onset of menses and often dissipates once menstrual flow is established. During the menstrual cycle, the breast undergoes significant histologic changes as described by Vogel et al. (see the section on Menstrual Cycle).³¹ During the secretory phase, luminal cells produce apocrine secretions and the stromal cells become edematous, which may contribute to the pathogenesis of breast pain. However, the exact physiologic events are not understood completely. Furthermore, while most women do experience mild cyclical breast pain, it is not clear why others have more pronounced pain. Cyclical breast pain is typically bilateral and involves the upper outer aspect of the breasts with radiation to the axillae or down the arms.

Noncyclical breast pain is more frequently unilateral and variable in its location in the breast. Possible etiologies include large pendulous breasts with pain resulting from stretching of the Cooper's ligaments, duct ectasia, macrocysts, medications (including antidepressants, hormones, and antibiotics), and infections.^{53,54} Thrombophlebitis of the lateral thoracic or superior thoracoepigastric vein (Mondor disease) is an uncommon presentation for breast pain characterized by a tender subcutaneous cord in the lateral aspect of the breast (Fig. 74-12). Mondor disease may result from trauma, radiation to the breast, and/or breast surgery. It can also occur in women with nonpalpable breast cancers, and a

mammogram should be obtained when diagnosed.⁵⁵ For symptomatic relief, a patient can use anti-inflammatory medications, although Mondor disease often resolves spontaneously without the need for a specific therapy. Referred pain to the breast from the chest wall or ribs can also occur. Spinal or paraspinal problems and medical conditions (biliary, pulmonary, esophageal, and cardiac disease) can also result in referred pain.

Figure 74-11. Oil cysts. The calcified rims of these cysts in a patient with a history of trauma are diagnostic.

Figure 74-12. Mondor disease. Thrombophlebitis of the thoracoepigastric vein causes retraction of the lateral portion of the breast, which crosses to the midline at the inferior areolar margin and is accompanied by a palpable cord.

The workup for breast pain should include a careful history, including questions related to the menstrual cycle, a thorough physical examination, and in women 35 years of age and older, a mammogram. If a malignancy is suspected, biopsy should be performed. If the CBE and diagnostic imaging studies are normal, reassurance that the symptoms are not consistent with breast cancer often provides significant relief for the patient.

Initial therapy for idiopathic breast pain includes lifestyle changes, the use of supportive garments such as a well-fitting brassiere with a steel underwire, a low-fat high-carbohydrate diet, and elimination of caffeine and nicotine. Oral analgesics with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) should be initiated. Topical analgesic gels containing diclofenac or salicylate can be applied to the affected breast areas. If a patient is on oral contraceptives or hormone replacement therapy, discontinuation of these medications may improve pain. However, in women not using oral contraceptives with cyclical breast symptoms, the initiation of this therapy has been shown to reduce breast pain severity and duration. Although inconclusive evidence exists for the role of evening

primrose oil (3,000 mg daily),^{56,57} it is often part of the initial therapeutic approach. Evening primrose oil needs to be taken for at least 4 to 6 months to achieve a positive effect.

Approximately 5% of women will still have debilitating breast pain despite lifestyle changes and the initial therapies described above. For these women, therapies such as danazol, tamoxifen, bromocriptine, and gonadotropin-releasing hormone (GnRH) agonists can be considered. However, only danazol has been approved by the FDA for the treatment of idiopathic breast pain. Danazol (100 mg to 400 mg daily) is an antigonadotropin that results in a hypoestrogenic state. However, its use is often discontinued as it also induces a hyperandrogenic state, with most women having side effects of increased facial hair, acne, deepening of the voice, and adverse blood lipid profiles.⁵⁸ Tamoxifen (10 mg daily) has also been shown to be effective although side effects, including the risk of blood clots, endometrial cancer, and hot flashes limit its use.⁵⁹ As both danazol and tamoxifen have significant teratogenic effects, women on these therapies must be counseled to use an effective birth control method. Although bromocriptine and GnRH agonists have been studied for use in breast pain, they are not currently recommended because of significant side effects. Therapies that have been proven to be ineffective include diuretics, progesterone, and vitamins. Surgery to excise trigger spots (in the absence of an identifiable lesion) is not recommended, as the affected area is often replaced by a painful scar.

Nipple Discharge

Nipple discharge is a common breast symptom that often results in surgical consultation. The most common cause of pathologic nipple discharge is an intraductal papilloma, but breast cancer can also present as a pathologic nipple discharge. The first step in evaluation of nipple discharge is to determine whether the nipple discharge is pathologic or physiologic. Physiologic discharge is nonspontaneous or is elicited by manual compression of the nipple. It often involves multiple ductal orifices in the nipple and is present in both breasts. The discharge is commonly white or clear (although it can also present as yellow, green, brown, or gray fluid) and is negative on occult blood test. In contrast, pathologic nipple discharge is spontaneous, is present in a single breast/ductal orifice, and is often positive on occult blood test. However, any nipple discharge that is spontaneous is considered pathologic. Age is also predictive of breast cancer risk in women with nipple discharge. In a study involving women with pathologic nipple discharge, breast cancer was present in 3% of women younger than 40 years, 10% in those 40 to 60 years of age, and 32% in those older than 60 years.⁶⁰

Clinical evaluation of nipple discharge includes a careful history and physical examination. The history includes questions regarding whether the discharge is spontaneous or elicited, unilateral or bilateral. The patient should be questioned regarding any recent trauma to the breast. The medical history and medications are reviewed. Medications such as oral contraceptives, metoclopramide, phenothiazines, and selective serotonin reuptake inhibitors can be associated with nipple discharge. A premenopausal woman presenting with milky fluid discharge bilaterally or galactorrhea should be evaluated for endocrine disease. Hypogonadism as suggested by amenorrhea or hot flashes/vaginal dryness should prompt a workup for hyperprolactinemia. In addition, hypothyroidism, pituitary adenoma, and chest trauma (including thoracotomy) can result in galactorrhea. When endocrine disease is suspected, patients should undergo laboratory evaluation including quantitative hCG, prolactin level, and thyroid function tests. The physical examination should include a visual field test as often these patients may show signs of bitemporal field loss or chiasmal syndrome. A careful breast examination is performed to evaluate for any dominant masses, skin changes such as eczema/infections, nipple changes such as Paget disease, or adenopathy. Each of the quadrants of the involved breast is massaged from the periphery to the nipple areolar complex and then pressure is applied to the base of the nipple areolar complex to elicit discharge. This will help define the involved quadrant of the breast and whether the discharge is from a single ductal orifice. The color of any nipple discharge should be noted, and an occult blood test should be performed.

Figure 74-13. Ductogram. A large defect (*arrows*) represents an intraductal papilloma.

After initial evaluation, no further workup is required in women who have physiologic discharge, and these women should be advised to avoid manual compression of the nipples.

Imaging evaluation is indicated for patients with pathologic nipple discharge and includes an ultrasound, and for patients older than 30 years, a mammogram is also recommended. In patients with an imaging abnormality, a biopsy should be considered. Additional diagnostic tests that may be helpful include ductography and ductoscopy. Ductography is performed by instilling contrast medium into the involved duct to identify any lesions in the ductal system. Lesions will appear as a complete ductal obstruction, irregularities in the duct wall, or as an intraductal filling defect (Fig. 74-13). However, the absence of a lesion on ductography does not rule out a cancer.⁶¹ Ductoscopy is often performed in the operating room and involves the use of a small fiberoptic ductoscope that is placed into the involved duct. The benefit of ductoscopy is that it allows for direct visualization of any potential lesions, which may result in more precise excision.

The most common etiology of pathologic nipple discharge is a papilloma, which is a benign epithelial lesion with supporting stroma that grows within a duct. When a papilloma is diagnosed by core biopsy, the standard recommendation is to proceed with surgical excision as it may be associated with atypia or ductal carcinoma in situ (DCIS). Other causes for pathologic nipple discharge include malignancy (most commonly DCIS, 5% to 15% of cases) and duct ectasia, which is characterized by ductal dilatation with loss of elastin in the duct walls and the presence of chronic inflammatory cells. It is not known, however, whether the inflammatory cells result from a primary or secondary infection and antibiotics are not recommended.

If a malignancy is identified as the etiology of a pathologic nipple discharge, it should be managed accordingly with the appropriate cancer surgery typically as the first treatment. In the absence of a known malignancy, pathologic nipple discharge should be treated with terminal duct excision. Prior to excision, the patient should refrain from any nipple stimulation. If the involved duct can be identified intraoperatively, a lacrimal duct or instillation of methylene blue may aid with the duct excision. Terminal duct excision is commonly performed with a circumareolar incision and involves removal of the duct from its proximal to distal extent, which is often a distance of 2 to 3 cm. Alternatively, ductoscopy can be performed as previously prescribed and then the outer sheath of the cannula can be left in place as a guide for surgical excision of the involved duct. If there is difficulty isolating the involved duct or multiple ducts are involved, central or total terminal duct excision may be indicated. The potential risks of terminal duct excision include inability to breast-feed and hyposensitivity or hypersensitivity of the nipple.

Breast Infections

Breast infections are uncommon outside of the postpartum period. As such, breast infections can be classified as lactating or nonlactating infections. Lactating breast infections occur commonly during the initial 6 weeks of breast-feeding and during the process of weaning. In the initial stages of infection, a mastitis or cellulitis is typically found, with associated pain, erythema, induration, and fever. A woman should not be counseled to discontinue breast-feeding. Commonly, the cellulitis results from *Staphylococcus aureus*. Treatment includes pain management (acetaminophen, NSAIDs) and an antibiotic

such as dicloxacillin. Alternative antibiotics include cephalexin and erythromycin. The mastitis should improve within 24 to 48 hours after initiation of antibiotics. If symptoms or fever persists, an abscess should be ruled out. For small or superficial abscesses, needle aspiration may be attempted. However, incision and drainage should be considered for large or complex abscesses, understanding the risks associated with milk fistula formation.

Nonlactating breast infections can present as periareolar abscesses or less commonly as peripheral abscesses. For small abscesses (less than 3 cm), needle aspiration and/or drain placement can be performed. However, for larger and/or deeper abscesses, incision and drainage may be indicated. This is commonly performed in the operating room under general anesthesia, although if the abscess is superficial or small, it may be possible to perform the incision and drainage at the bedside with infiltration of a local anesthetic. A preoperative ultrasound can be obtained to better evaluate the size and location of the abscess. The patient is placed in supine position and the surgical site is prepped and draped in the usual sterile fashion. Palpation of the abscess is performed, then using a no. 11 blade scalpel, a skin incision is made directly over the abscess. Often, the abscess is not located directly under the area of greatest erythema, and careful breast examination should be performed to localize the area of greatest fluctuance. Using a Kelly or Burlisher clamp, loculations are broken up in the cavity to fully drain the abscess. *Biopsy of the cavity should always be considered, as breast infection may be an unusual breast cancer presentation.* The abscess cavity is then copiously irrigated. For a subareolar abscess, removal of the sinus tract as well as the segmental duct should be considered. If the abscess is small, no packing is necessary. However for larger abscesses, we advocate loosely packing the wound with wet to dry gauze, which should be changed daily. Alternatively, an advanced wound care dressing can be used. The amount of the packing should be decreased daily and usually after 1 week, no further packing is needed. Alternatively, the incision can be loosely approximated with interrupted 4-0 nylon sutures leaving a 1.5-cm opening for a Penrose drain to be placed. The drain and the sutures should be removed within 4 to 7 days. Antibiotic, such as cephalexin 500 mg QID, is commonly prescribed for 7 to 10 days postoperatively, although once a wound is properly drained and cellulitis subsides, the patient can discontinue all antibiotics. For chronic subareolar abscesses, it may be necessary to completely excise the involved duct. During an acute exacerbation, patients are first treated with antibiotics and during the resolution phase, surgical excision is performed. Intraoperatively, the infected duct or fistula is identified using a lacrimal duct probe. A radial elliptical incision is then made incorporating the entire duct from the nipple to the subareolar breast tissue. Excision is then performed with care to fully dissect the subareolar duct system from the underlying breast tissue. Interrupted suture of 4-0 plain gut is then used to reapproximate the nipple from its apex to its base. The deep dermal layer of the skin is then reapproximated with 3-0 Vicryl sutures and the skin closed in a subcuticular fashion with 4-0 monocryl. The patient should be continued on antibiotics for an additional 2 weeks.

In the setting of recurrent or persistent abscess formation or inflammatory changes despite adequate surgical management, other etiologies need to be considered including idiopathic granulomatous mastitis, Wegener’s granuloma, sarcoidosis, tuberculosis, and histoplasmosis.

BENIGN BREAST DISEASE

Benign breast lesions can be classified into three groups: (1) nonproliferative breast lesions, (2) proliferative breast lesions without atypia, and (3) proliferative breast lesions with atypia (Table 74-4).

Nonproliferative Breast Lesions

Nonproliferative breast lesions include breast cysts, papillary apocrine change, epithelial-related calcifications, and mild hyperplasia of the usual type. These lesions are not associated with an increased risk of breast cancer.⁶² Papillary apocrine change is characterized by proliferation of ductal epithelial cells that show apocrine features and have eosinophilic cytoplasm. Benign calcifications found in normal ducts, lobules, breast stroma, and blood vessel walls are referred to as epithelial-related calcifications. Mild hyperplasia of the usual type occurs when the number of epithelial cells within a duct is more than two but not more than four cells in depth, and the epithelial cells do not cross the lumen of the involved space.⁶³

CLASSIFICATION

Table 74-4 Classification of Benign Breast Disease

Nonproliferative: No Increase In Risk
Cysts: micro or macro
Ductal ectasia
Simple fibroadenoma
Mastitis
Fibrosis
Metaplasia: squamous or apocrine
Mild hyperplasia
Proliferative: RR 1.5–2.0
Complex fibroadenoma
Papilloma
Sclerosing adenosis
Hyperplasia: moderate or severe
Proliferative With Atypia: RR 4.5–5.0
Atypical ductal hyperplasia
Atypical lobular hyperplasia

RR, relative risk.

The most common nonproliferative lesions of the breast are cysts, which often present clinically as solitary masses that can be associated with pain. They are fluid-filled round or ovoid structures arising from the terminal duct lobular unit when fluid accumulates because of distension and obstruction of the efferent ductule.⁶⁴ Given that cysts arise from lobular pathology, they occur mainly during lobular development, menstrual cyclic changes, and lobular involution in premenopausal and postmenopausal women, with peak incidence between 35 and 50 years of age.^{65,66}

The three types of cysts are simple, complicated, and complex. Simple cysts are well circumscribed and on ultrasound have posterior acoustic enhancement. In addition, they are anechoic and do not have solid components or Doppler signals. If simple cysts are diagnosed by ultrasound, they are by definition benign and do not require further intervention, although cyst aspiration can be performed if the patient is symptomatic. Alternatively, FNA can also be used to diagnose simple cysts. If the aspirated fluid is nonbloody and the palpable mass completely resolves, this is also diagnostic of a simple cyst and no further diagnostic evaluation is required. A follow-up CBE with or without ultrasound can be performed in 3 to 6 months to document stability, and the patient may resume routine breast cancer screening.

Unlike simple cysts that are not associated with malignancy, complicated and complex breast cysts are associated with malignancy in <1% and 1% to 23%, respectively.^{67–69} On ultrasound, complicated cysts appear as masses with homogenous low-level internal echoes due to echogenic debris. However, there are no solid components, thick walls, or thick septa. Complex cysts are defined as cysts with solid components, thick walls, or thick septa. Complex cysts are characterized on ultrasound by the absence of posterior wall enhancement and the appearance of anechoic and echogenic components. Complicated cysts can be confirmed as benign by biopsy through FNA, core biopsy, or excisional biopsy. Alternatively, ultrasound imaging and mammography (if the lesion was visualized on mammography) with CBE every 6 months for 2 years can be performed to document stability. If complicated cysts develop any concerning changes such as an increase in size or development of a solid component, biopsy should be performed.⁷⁰ Complex cysts mandate biopsy. If no fluid is aspirated by FNA, then core biopsy under image guidance should be performed with care to biopsy the solid component. A metallic clip marking the biopsy site facilitates surgical excision if necessary and facilitates follow-up imaging. If pathology is concordant with imaging findings, then follow-up with CBE and ultrasound imaging every 6 to 12 months for 1 to 2 years can be performed to document stability. For any concerning changes in the appearance of the lesion or increase in size, excisional biopsy should be performed. In patients who may be noncompliant with follow-up care, surgical excision should be considered for complicated and complex breast cysts.⁷⁰

Proliferative Breast Lesions without Atypia

Proliferative breast lesions without atypia include ductal hyperplasia, intraductal papillomas, sclerosing adenosis, radial scars, and fibroadenomas. Ductal hyperplasia is often an incidental finding noted on biopsies obtained for mammographic abnormalities or for breast masses. Ductal hyperplasia is characterized by an increased number of cells within the ductal space; however, the cells retain the cytologic features of benign cells. Ductal hyperplasia is not associated with a significant risk for

subsequent breast cancer and no additional treatment is necessary.^{63,71} Women with intraductal papillomas often present with pathologic nipple discharge (see section on Nipple Discharge above). These lesions consist of a monotonous array of papillary cells that grow from the wall of a duct or cyst into its lumen. Given that intraductal papillomas can harbor areas of atypia or DCIS, surgical excision is recommended when intraductal papillomas are diagnosed by core needle biopsy. If no atypia or DCIS is found at the time of excision, then no further treatment is necessary.⁷²⁻⁷⁶ Sclerosing adenosis typically presents as a mammographic abnormality or a mass and requires no further treatment following biopsy, as it is a benign lobular lesion resulting from increased fibrous tissue and interspersed glandular cells.^{77,78} Complex sclerosing lesions or radial scars are often found incidentally when a breast mass or radiologic abnormality is biopsied or excised. These lesions are characterized by a fibroelastic core with radiating ducts and lobules, and radial scars can appear spiculated on mammography.⁷⁹ When diagnosed on core biopsy, radial scars should be excised as 8% to 17% are associated with malignancy at surgical excision.⁸⁰⁻⁸² If the surgical excisional biopsy confirms a radial scar, no additional treatment is needed.

Fibroadenomas typically present as well-circumscribed mobile masses that are not fixed to the surrounding breast tissue. They are benign solid tumors made of glandular as well as fibrous tissue and are found most commonly in women between the ages of 15 and 35 years.⁸³ Fibroadenomas with benign imaging characteristics can be followed with serial CBE and ultrasound imaging to ensure stability. Alternatively, core needle biopsy can be performed to confirm the diagnosis. If a fibroadenoma is asymptomatic, surgical excision is not necessary. However, if the presumed fibroadenoma is symptomatic or increases in size, excision can be performed for symptomatic relief or to rule out a malignancy such as a phyllodes tumor.⁸⁴ Fibroadenomas that are associated with proliferative changes such as sclerosing adenosis, ductal epithelial hyperplasia, epithelial calcification, or papillary apocrine changes are referred to as complex fibroadenomas. Surgical excision of these lesions is often recommended to exclude a diagnosis of breast cancer,^{85,86} although this is controversial as some advocate that these lesions can be followed similarly as simple fibroadenomas.⁸⁷

A fibroadenoma that is greater than 10 cm in size is referred to as a giant fibroadenoma and excision is recommended, as these lesions are hard to differentiate from a phyllodes tumor.⁶³ Juvenile fibroadenomas occur in young women between the ages of 10 and 18 years and can vary in size from 5 to 20 cm in diameter. Surgical excision is recommended as these lesions can be cosmetically distressing for the young patient and are difficult to differentiate from a phyllodes tumor, although risk to the prepubertal breast bud is a potential complication.⁸⁸

Proliferative Breast Lesions with Atypia

Proliferative breast lesions with atypia include ADH, ALH, flat epithelial atypia (FEA), and LCIS. Although these lesions are not considered premalignant, they are associated with an increase in the patient's future risk of developing breast cancer (Fig. 74-14).

ADH is characterized by a proliferation of uniform epithelial cells with monomorphic round nuclei filling part, but not all, of the involved duct. ADH often presents as suspicious microcalcifications seen on mammography. In contrast, ALH is often an incidental finding found on breast biopsies performed for other reasons, such as an abnormal mammogram or breast mass. ALH is characterized by a proliferation of monomorphic, evenly spaced, dyshesive cells filling part, but not all, of the involved lobule.⁶³ Atypical hyperplasias are associated with an increased risk of subsequent breast cancer (relative risk [RR] 3.7 to 5.3) in both the ipsilateral breast and the contralateral breast.⁸⁹⁻⁹³ In the past atypical hyperplasias (both ductal and lobular) that are diagnosed on core needle biopsy mandated a surgical excisional biopsy to exclude a diagnosis of malignancy. In case of atypical ductal hyperplasia, a surgical excisional biopsy is still recommended as an upgrade to DCIS or invasive breast cancer can occur in 10% to 20% of cases. However, in regards to lobular neoplasias (atypical lobular hyperplasia and LCIS), more recent evidence suggests that an association with malignancy may be as low as 1% (central pathology review) and 3% (local pathology review) and as such surgical excision for these lesions are no longer indicated.⁹⁴ If the diagnosis of atypical hyperplasia is made by excisional biopsy and the area is adequately sampled, reexcision is not necessary or recommended. Instead, the patient should be counseled toward risk reduction strategies that include CBE every 6 to 12 months, annual screening mammography, and consideration for chemoprevention with a selective estrogen receptor modulator (SERM) or an aromatase inhibitor (AI).⁷⁰ In addition, the patient should be counseled to perform consistent breast self-examinations (BSEs) such that she will become familiar with her breasts and report changes promptly to her provider (see the section on Management of Patients at High Risk for Breast Cancer later).

Figure 74-14. Cumulative risk for the development of invasive breast cancer after a biopsy for benign breast disease. Women with atypical hyperplasia (ductal or lobular type) are at a significantly increased risk for the development of breast cancer. (Reproduced with permission from Page DL, Dupont WD. Anatomic markers of human premalignancy and risk of breast cancer. *Cancer* 1990;66:1326.)

Lobular Carcinoma In Situ

LCIS is a noninvasive lesion that arises from the lobules and terminal ducts of the breast. It is characterized by solid proliferation of small cells, with small, uniform, round to oval nuclei, and variably distinct cell borders. The cytoplasm of the cells are clear to lightly eosinophilic and occasionally there are intracytoplasmic vacuoles that may be large enough to produce signet ring cell forms. LCIS tends to have a very low proliferative index and is estrogen-receptor positive.⁹⁵ LCIS is more prevalent in premenopausal women and white women.^{96,97}

3 LCIS is often diagnosed as an incidental finding on a breast biopsy that has been performed for another reason, such as an area of fibrocystic change or mammographic abnormality. Traditionally, if LCIS is identified on core biopsy, surgical excision is performed to exclude an associated cancer.⁹⁷⁻¹⁰¹ However, more recent data suggests that this potential upgrade to DCIS or invasive cancer is likely 1% to 3% and as such surgical excision is no longer indicated.^{94,98-102} If LCIS is found on excisional biopsy, no further surgical intervention is needed. However, if *pleomorphic* LCIS is identified at a surgical margin on excisional biopsy, wide excision with negative margins is recommended as pleomorphic LCIS can be hard to differentiate from DCIS.¹⁰³⁻¹⁰⁵

RESULTS

Table 74-5 Risk for Breast Cancer Development After Lobular Carcinoma in Situ

Study	No. Patients	Invasive Cancer (%)	Follow-Up (yrs)	Relative Risk
Haagensen ¹⁰⁶	287	18	16.3	6.9
Rosen et al. ¹⁰⁷	99	12.5	24	9.0
Andersen ¹⁰⁸	47	26.4	15	12.0
Page et al. ⁹²	44	23	18	9.0
Salvadori et al. ¹⁰⁹	80	6.3	5	10.3
Ottesen et al. ¹¹⁰	69	11.6	5	11.0
Bodian et al. ¹¹¹	236	26 ^a	18	5.4
Fisher et al. ¹⁶³	182	33	5	—

^aIncludes intraductal and invasive cancer.

Although it is not a premalignant lesion, LCIS conveys a substantial increased risk for breast cancer. The RR of developing an invasive cancer in women with LCIS is approximately two- to threefold higher than that in women without LCIS (Table 74-5).¹¹² LCIS also conveys an increased risk for breast cancer to the contralateral breast. Historically, women diagnosed with LCIS were treated with bilateral prophylactic mastectomies. Most experts today consider this approach to be too aggressive given that *most* women with LCIS who do not have other contributory factors (e.g., family history of premenopausal breast cancer) will not develop an invasive breast cancer. Instead, a careful lifetime

surveillance protocol similar to that described above for atypical hyperplasias can be followed. Chemoprevention with a SERM and/or AI can also be discussed with the patient. There are currently no randomized trials to compare the efficacy of surveillance protocol versus prophylactic mastectomy in women with LCIS.

FEA is an intraductal finding that is characterized by the replacement of native epithelial cells by a single layer, or up to 3 to 5 layers of mildly atypical cells (World Health Organization definition).¹¹³ When diagnosed on core biopsy, the risk of upgrade to a malignancy at surgical excision is 5% to 15%.^{114–116} When FEA is diagnosed by excisional biopsy, no further surgery is warranted. However, if FEA is diagnosed by core needle biopsy, excisional biopsy should be performed. Alternatively, radiologic surveillance can be performed and if there is absence of a residual mammographic abnormality and core biopsy was felt to be adequate, no further surgery is needed. Excisional biopsy must be performed for any residual lesions seen. When FEA is found at the margins, wider excision is not needed.^{114–117} Although FEA is an atypia, it conveys the same risk of breast cancer that is associated with benign proliferative disease without atypia and as such, patients should continue routine surveillance.¹¹⁸ There are also no data to support the use of chemoprevention.

BREAST CANCER SCREENING

Breast Self-Examination

BSE has not been shown to have an impact on the rates of breast cancer diagnosis, stage at diagnosis, or breast cancer mortality. In addition, BSE may result in higher rates of breast biopsy for benign disease. The largest study conducted was the Shanghai randomized trial involving 266,064 women who were assigned to either a BSE instruction group or a control group. The BSE group received instruction on BSE with reinforcement sessions 1 and 3 years later, supervised self-examination every 6 months for 5 years, and ongoing reminders. Intensive instruction on BSE did not reduce mortality from breast cancer but increased the rate of biopsy for benign disease.¹¹⁹ A review of eight other studies had similar findings.¹²⁰ The US Preventive Services Task Force (USPSTF), the Canadian Task Force on Preventive Health Care (CTFPHC), the National Comprehensive Cancer Network (NCCN), and the World Health Organization do not recommend that women receive instruction on BSE. The American Cancer Society recommends that women be educated about the benefits and limitations of BSE. The American College of Obstetricians and Gynecologists recommends breast self-awareness, which can include BSE. In women who are not at high risk for breast cancer, we do not advocate for or discourage the use of BSE; however, we do promote breast self-awareness. Proper examination technique should be reviewed for women who are already routinely performing BSE, for women at high risk for the development of breast cancer, and for breast cancer survivors.

Clinical Breast Examination

Women should undergo CBE as part of their annual physical examination. However, it is difficult to determine the effectiveness of CBE as a screening tool as it is often performed with mammography. It has been suggested that CBE may modestly improve early detection of breast cancer but at the risk of increased false-positives.^{121,122} The effectiveness of CBE has not been proven by well-designed large clinical trials.¹²³ As such, the USPSTF, the Canadian Task Force on Preventive Health Care, and the World Health Organization do not support CBE. The American Cancer Society and the American College of Obstetricians and Gynecologists recommend CBE every 3 years. We feel that CBE is critical to the evaluation of breast disease, as such, providers of women's health have to become experts in this technique.

Screening Mammography

Screening mammography is widely performed but is not without controversy. Although systematic reviews of randomized trials have found a significant reduction in breast cancer mortality with mammographic screening in women aged 40 to 69 years, most of these studies were conducted before 1990, and there is concern that the current reduction in mortality is less as these trials were performed in an era prior to the adoption of modern treatment paradigms (multidisciplinary care and the use of adjuvant systemic treatments). In 2012, a meta-analysis of 11 randomized trials determined that the RR of breast cancer mortality for women undergoing screening mammography was 0.80 (95% confidence interval [CI], 0.73 to 0.89) compared with controls. This correlates with a RR reduction of 20%.¹²⁴ In

2014, the Canadian National Breast Screening Study concluded a 25-year follow-up analysis. The cumulative mortality from breast cancer was similar between women randomized to the mammography arm or to the control arm. For women aged 40 to 49 years, they were randomly assigned to mammography or usual care, and for women aged 50 to 59 years, they were randomly assigned to mammography plus CBE or to CBE alone. As such, the study concluded that annual mammography in women aged 40 to 59 years does not reduce mortality from breast cancer beyond that of physical examination or usual care in the era of modern adjuvant therapy. In addition, they reported that 22% (106/484) of screen-detected invasive breast cancers were overdiagnosed.¹²⁵ The primary risk of screening mammography is false-positive test results, which can result in patient anxiety, overdiagnosis, increased medical costs, and unnecessary biopsies.

Algorithm 74-4. Management of the patient with an abnormal screening mammogram. When pathology is benign, concordance or discordance with imaging findings dictates whether surgical excisional biopsy is indicated.

4 All expert groups in North America agree that screening mammography should be performed in women 50 years of age and older. However, differences exist about whether screening should be performed between 40 and 49 years of age. The American Cancer Society, the American College of Radiology, the American Medical Association, the National Cancer Institute, the American College of Obstetricians and Gynecologists, and the NCCN all support starting routine screening mammography at the age of 40 years. Other groups including the USPSTF, the American College of Physicians, and the CTFPHC recommend initiating screening at the age of 50 years. Although most groups agree with continuing screening until the age of 74 years, some recommend stopping screening after the age of 74 years (USPSTF and the CTFPHC). Others feel that this decision should be individualized (the American College of Obstetricians and Gynecologists and the American College of Radiology). The frequency of mammography (annually or biennially) has also been debated among the various expert groups; however, most groups in North America advocate for annual screening. Until further studies are performed, we continue to recommend annual screening mammography starting at the age of 40 years.

Routine mammography consists of two views (craniocaudal (CC) and mediolateral oblique (MLO)) of each breast. Breast positioning is instrumental to mammography, with the CC view obtained by lifting the breast and positioning it on the plate with compression applied from above, whereas the MLO view

is obtained with the breast being compressed from the side. These images are then evaluated and classified according to the American College of Radiology breast imaging reporting and data system (BI-RADS)¹²⁶ (Algorithm 74-4) (Table 74-6). Screening mammography with a completely negative examination is classified as BI-RADS 1. Screening mammography with benign findings such as a cyst or a fibroadenoma is classified as BI-RADS 2. If any indeterminate or concerning findings exist on screening mammography requiring additional diagnostic imaging, then a BI-RADS 0 is assigned. Probable benign findings are classified as BI-RADS 3 with a typical recommendation of repeat imaging in 6 months. Suspicious abnormalities are classified as BI-RADS 4 or 5 with recommendation for biopsy. Screening mammography is a relatively sensitive but nonspecific test, and only 20% to 30% of abnormalities found ultimately prove to be malignant (Fig. 74-15). Methods to increase the specificity of mammography include computer- aided detection (CAD) and more recently breast tomosynthesis. CAD is a computer-based technology that recognizes mammographic patterns and assists breast imaging specialists in identifying areas of concern. Its use has been approved by the FDA since 1998.¹²⁷ More recently, the FDA approved breast tomosynthesis, also known as 3-D mammography, for routine clinical use as an adjunct to digital mammography with early findings suggesting a decrease in recall rate and an increase in cancer detection rate.¹²⁸

CLASSIFICATION

Table 74-6 BI-RADS Classification of Mammographic Abnormalities

Category	Assessment	Recommendation
1	Negative	Routine screening
2	Benign finding	Routine screening
3	Probably benign finding	Short-interval follow-up
4	Suspicious abnormality	Tissue diagnosis
4A	Low suspicion for malignancy	
4B	Moderate suspicion for malignancy	
4C	High suspicion for malignancy	
5	Highly suggestive of malignancy	Tissue diagnosis
6	Known biopsy proven malignancy	Appropriate action should be taken

BI-RADS, breast imaging reporting and data system.

Screening MRI

Screening MRI is more sensitive but less specific than mammography. It is commonly used by providers as an adjunct to mammography to screen women at high risk for breast cancer; however, the effect of MRI screening on survival in high-risk groups has not been supported by any prospective randomized trial. The American Cancer Society does recommend offering annual MRI in addition to mammography to women within certain high-risk groups, such as those with BRCA mutations, first degree relatives of known BRCA mutation carriers, and those with a lifetime risk of breast cancer that is estimated to be 20 percent or higher based on risk prediction models (see the section on Management of Patients at High Risk for Breast Cancer). The NCCN has similar recommendations and also includes patients who received radiation treatment to the chest between ages 10 and 30 and those who have TP53 (Li–Fraumeni syndrome) or PTEN genetic (Cowden syndrome) mutations. The National Institute of Health and Care Excellence (UK) has similar recommendations, advocating for MRI in high-risk patients. Providers who choose to screen with MRI and mammography often do so in a staggered fashion such that the patient is undergoing imaging every 6 months.

MANAGEMENT OF PATIENTS AT HIGH RISK FOR BREAST CANCER

Risk Factors

Breast cancer is the most common cancer in women in the United States. Approximately 200,000 women and 2,000 men are diagnosed with invasive breast cancer each year.¹²⁹ Breast cancer is the most common cancer in women of every major ethnic group, and the highest rate is among Caucasian women, with 122 newly diagnosed breast cancer cases per 100,000 women each year.¹³⁰ Understanding the risk factors for breast cancer is important, as some of these risks can be modified to decrease a

patient's risk through lifestyle/behavioral changes and/or the use of chemoprevention.

Figure 74-15. Workup of abnormal screening mammogram. **A:** Craniocaudal view showing an increased density with a slightly spiculated appearance (*arrow*). **B:** Spot magnification view of the density demonstrating normal breast tissue.

Increasing Age

As a woman ages, her risk for breast cancer increases: birth to age 49 years, 1.9% probability of developing invasive breast cancer (1 in 53); age 50 to 59 years, 2.3% (1 in 43); age 60 to 69 years, 3.5% (1 in 29); and age 70 years and older, 6.7% (1 in 15). From birth to death, the probability of developing invasive breast cancer is 12.3% or 1 in 8.¹²⁹

Estrogen Exposure

A woman's lifetime exposure to estrogens appears to correlate with her risk for breast cancer.¹³¹ Exposure to estrogens can be approximated by age of first menarche, age of menopause, and age of first live birth, with nulliparous women who have an early menarche and a late menopause having the highest risk. Premenopausal women who undergo bilateral oophorectomy are at decreased risk. Given that high endogenous levels of estrogen is known to increase the risk of breast cancer in both premenopausal and postmenopausal women, the use of exogenous hormones and their associated risk for breast cancer has been studied and debated. The use of hormonal contraceptives does not appear to significantly increase the risk of breast cancer.¹³² However, the use of hormone replacement therapy in postmenopausal women has been associated with an increased risk of breast cancer as reported in the Women's Health Initiative Estrogen Alone and Estrogen-Plus-Progestin Studies, which were stopped early secondary to this and other concerns.¹³³ In the Estrogen-Plus-Progestin study, the HRT used was a combined estrogen-progestin therapy (EPT) that was given to postmenopausal women with an intact uterus. The risk of breast cancer is relatively low, as EPT would result in an additional eight cases of breast cancer if 10,000 women took EPT for a year. More recently, it was determined that the rate of death from breast cancer among those taking EPT was 2.6 per 10,000 women per year, compared with 1.3 per 10,000 women per year among those taking placebo.¹³⁴ Short-term use for less than 3 years does not appear to significantly increase the risk of breast cancer and after the cessation of EPT use for 3 years, a woman's risk returns to baseline.

Given that lactation interrupts ovulation and modifies pituitary and ovarian hormone secretion, it has been postulated that breast-feeding can reduce breast cancer risk. This finding remains inconclusive. Limited data suggest that longer duration of lactation in premenopausal women may reduce risk.¹³⁵ A pooled analysis consisting of more than 50,000 women with breast cancer and 96,000 controls concluded that for every 12 months of breast-feeding, there was an associated 4.3% reduction in the RR of breast cancer.¹³⁶

Environmental and Lifestyle Factors

Women who were subjected to ionizing radiation of the chest, such as for treatment of Hodgkin lymphoma or through exposure from nuclear plant accidents or the atomic bomb, have an increased risk of breast cancer. The prepuberty stage (age 10 to 14 years) appears to be the most vulnerable time for

exposure, with little associated risk when exposure occurs after age of 45 years.^{137–139} Alcohol use is associated with an increased risk of breast cancer and correlates with the amount of consumption, with differences noted with alcohol intake as low as three drinks per week versus those who abstain from alcohol. A meta-analysis of 110 studies shows a small but significant association (RR, 1.05; 95% CI, 1.02 to 1.08).^{140,141} The relationship between cigarette use and breast cancer risk remains controversial because of unresolved issues of confounding and dose response; however, a recent meta-analysis found that smoking before menarche and before the first birth was associated with an increased risk for breast cancer.¹⁴² Furthermore, in women diagnosed with breast cancer, lifetime cigarette smoking (≥ 20 pack-years) was associated with an increased risk of recurrence and all-cause mortality.¹⁴³ The role of dietary factors such as fat intake, red meat and processed meat, phytoestrogens, calcium/vitamin D, and antioxidants in modifying breast cancer risk remains inconclusive. Regular physical exercise and a diet composed mainly of fruits and vegetables likely provide protection against breast cancer.

Family History

The number of first-degree relatives with breast cancer is strongly associated with a woman's risk for the future development of breast cancer. If one first-degree relative is affected, the risk of breast cancer increases by approximately twofold, and if two first-degree relatives are affected, the risk of breast cancer is increased by approximately threefold. The age at diagnosis of the first-degree relative is also important, as a woman's risk is approximately threefold higher when the diagnosis occurs before age 30 but only 1.5-fold higher if the diagnosis is after age 60.¹⁴⁴

When evaluating family history, it is important to note that the majority of breast cancers are caused by sporadic mutations (mutations that occur in somatic cells that cannot be inherited). When studying the family tree of women with *sporadic breast cancer*, these women typically have no family history of breast cancer through two generations, including siblings, offspring, parents, and both maternal and paternal aunts, uncles, and grandparents. Less than 10% of breast cancers are hereditary. In families with *hereditary breast cancer*, the family tree is characterized by earlier onset of breast cancer, bilateral breast cancer, a greater frequency of primary cancers such as breast and ovary, and an autosomal dominant inheritance pattern (Fig. 74-16).¹⁴⁵ For women who have first- or second-degree relatives with breast cancer but do not meet the hereditary breast cancer definition noted above, these women have *familial breast cancer* where it is likely that both genetic and environmental factors play a role in their susceptibility.¹³⁷

Most patients with hereditary breast cancer have mutations in the *BRCA1* or *BRCA2* genes, which are localized to chromosome 17q21 and chromosome 13q12.3, respectively. Both serve as tumor suppressor genes and function as gatekeepers in controlling gene transcription, regulating repair of DNA damage (especially double strand breaks during cell replication), and may play a role in the maintenance of genomic stability.^{146–148} Founder mutations exist in the Ashkenazi Jewish population with specific mutations in *BRCA1* (185delAG, 5382insC) and *BRCA2* (617delT).¹⁴⁹ Other *BRCA*-specific mutations have been identified in Dutch, Scandinavian, French-Canadian, and Belgian populations.^{150,151}

The lifetime risk of breast cancer in *BRCA1* and *BRCA2* mutation carriers is estimated to be as high as 85%, which is markedly elevated from a baseline risk of 12% in the general population (Table 74-7). Ovarian cancer risk is higher in *BRCA1* carriers with an estimated risk of 40% to 60% whereas *BRCA2* carriers have a risk of 15%. Among male patients with breast cancer who have a *BRCA* mutation, one-third of mutations involve *BRCA1* and two-thirds involve *BRCA2*. The risk of breast cancer in males is 1% to 5% with a *BRCA1* mutation, and 5% to 10% with a *BRCA2* mutation, versus a risk of 0.1% in the general population.^{152–154} In addition, prostate and pancreatic cancer is more common in patients with *BRCA2* mutations.^{155,156}

Several commercial tests exist for *BRCA1* and *BRCA2* testing. Prior to genetic testing, patients should undergo genetic counseling where the complexities of testing are discussed along with potential emotional and financial ramifications that can result from positive test results. Ideally, genetic testing should start with a family member affected with breast or ovarian cancer or both. If that individual tests negative, further testing on an unaffected relative is unlikely to be informative. Candidates for gene testing include those with a known *BRCA1* or *BRCA2* gene mutation in the family, a personal history of breast cancer at age 45 or younger, a personal history of breast cancer at age 50 or younger and a family member (parent, sibling, child, grandparent, grandchild, uncle, aunt, nephew, niece or first cousin) diagnosed with breast cancer at any age, a personal history of triple negative breast cancer (TNBC) diagnosed at age 60 or younger, a personal history of ovarian cancer, a personal or family history of male breast cancer, and Ashkenazi Jewish heritage and a personal or family history of breast

or ovarian cancer.¹⁵⁷ Once an individual tests positive for a mutation, she should inform her first- and second-degree relatives of their risk status and the potential for DNA testing.

Figure 74-16. Pedigree of genetic breast cancer. The family illustrated in the pedigree carries a mutation of the *BRCA1* gene; multiple relatives are affected with breast and ovarian cancer.

Other breast cancer susceptibility genes include *p53*, *ATM*, *CDH1*, and *PTEN*. The Li–Fraumeni or SBLA syndrome corresponds with *p53* mutations and includes a broad spectrum of cancers including sarcoma, breast cancer and brain tumors, lung and laryngeal cancer, leukemia, lymphoma, and an adrenal cortical carcinoma.¹⁵⁸ The *ATM* gene mutation results in a childhood neurologic disorder referred to as ataxia–telangiectasia, which is characterized by progressive cerebellar and neuromotor deterioration, telangiectasia of the conjunctivae and facial skin, and growth retardation. Females with the *ATM* mutation have a five times higher risk for developing breast cancers than the general population.¹⁵⁹ Females with the *CDH1* or E-cadherin gene mutation have a 70% lifetime risk for diffuse gastric cancer and a 40% risk for lobular breast cancer.¹⁶⁰ Distinctive mucocutaneous lesions referred to as trichilemmomas characterize Cowden disease, which is associated with an increased risk of breast, thyroid, and genitourinary tract cancers in women, resulting from a *PTEN* gene mutation.¹⁶¹

Clinical Risk Assessment

Through large population studies, numerous factors that can increase breast cancer risk have been identified as summarized in Table 74-8. In an effort to quantitate these potential risks such that preventive strategies can be better tailored, multiple risk assessment tools have been developed including the BCRAT or the Gail model 2,¹⁶² BRCAPRO,¹⁶³ BOADICEA,¹⁶⁴ Tyrer-Cuzick,¹⁶⁵ and the Breast Cancer Surveillance Consortium.¹⁶⁶ The Gail model calculates risk over a defined time interval and predicts risk accurately in groups of women 35 years of age and older who undergo annual mammography. The model is not for women who have a strong family history of breast cancer (such as genetic mutation carriers) or those with LCIS. The components of the Gail model include current age, age at menarche, age at time of first live birth, number of first-degree relatives with breast cancer, number of prior breast biopsies, prior breast biopsy with atypia, and race. A sample risk calculation is shown in Figure 74-17. Women are considered to be at high risk if their 5-year risk is > 1.7%, or if their lifetime risk of breast cancer is at least 20%.

Table 74-7 Estimated Lifetime Cancer Risks for *BRCA1* and *BRCA2* Mutations (To Age 70)

Type of Cancer	General Population (%)	BRCA1 Carrier (%)	BRCA2 Carrier
Breast cancer	8.0	40–85	40–85
Contralateral breast cancer	0.5–1/yr	40–65	40–65
Male breast cancer	0.1	1–5	5–10
Ovarian cancer	1.4	30–45	10–20

CLASSIFICATION

Table 74-8 Magnitude of Known Breast Cancer Risk Factors

Relative Risk <2
Early menarche
Late menopause
Nulliparity
Proliferative benign disease
Obesity
Alcohol use
Hormone replacement therapy
Relative Risk 2–4
Age >35 first birth
First-degree relative with breast cancer
Radiation exposure
Prior breast cancer
Relative Risk >4
Gene mutation
Lobular carcinoma in situ
Atypical hyperplasia

Management

All women at high risk for breast cancer should undergo genetic counseling, with education provided about the risk factors, genetics, and natural history of breast cancer. These women should be followed with enhanced surveillance, and chemoprevention or prophylactic surgery should be considered. For women who have a genetic predisposition, such as those with a *BRCA1* or *BRCA2* mutation, many experts support aggressive surveillance including CBE biannually beginning at age 20 years and annual mammography and MRI screening performed in a staggered fashion such that imaging occurs every 6 months starting at age 25. The use of screening MRI for women at high risk is supported by numerous studies (see the section on Screening MRI). Prophylactic mastectomies can be considered at any age; many women prefer to defer this until after childbearing as they would like to breast-feed. Ovarian cancer screening for *BRCA1* and *BRCA2* carriers includes transvaginal ovarian ultrasound, serum CA-125, and annual pelvic examinations starting at age 30. When childbearing is complete, prophylactic oophorectomies should be considered. In women with a family history but no known genetic abnormality, screening mammography should begin 10 years before the age of onset in the youngest diagnosed first-degree relative or at age 40. Furthermore, in the absence of a genetic abnormality, women who have a lifetime risk of breast cancer >20% should also be monitored with annual screening MRI.

Figure 74-17. Breast cancer risk assessment according to the Gail model. This woman's 5-year risk for the development of breast cancer is 1.6%, and her lifetime risk is 18%.

In addition to its role in the treatment of breast cancer, endocrine therapy (chemoprevention) can reduce the risk of invasive and/or in situ breast cancers in women at high risk for breast cancer. Women who are known to benefit from chemoprevention include those older than 35 years with a history of LCIS, DCIS, or atypical proliferative lesions of the breast, women between 35 and 59 years of age with a Gail model risk of breast cancer $>1.7\%$ over 5 years, and women with known *BRCA1* or *BRCA2* mutations who do not undergo bilateral prophylactic mastectomies. Currently, there are no data regarding the risks and benefits of chemoprevention in male patients with breast cancer and as such, the use of these agents in men is not recommended.

For pre- and postmenopausal women at increased risk of breast cancer, both tamoxifen and raloxifene can be used. As selective estrogen receptor modulators (SERMs), both agents block the effects of endogenous estrogen on normal breast tissue and breast cancer. Using data from four trials in the 2013 USPSTF meta-analysis, tamoxifen has been shown to reduce the risk of estrogen receptor (ER)-positive breast cancer (RR, 0.70; 95% CI, 0.59 to 0.82). Similarly, using data from two trials in the 2013 USPSTF meta-analysis, raloxifene reduced the risk of ER-positive breast cancers (RR, 0.44; 95% CI, 0.27 to 0.71).^{167,168} In terms of the choice between tamoxifen and raloxifene, the STAR trial directly compared tamoxifen with raloxifene and showed that the former was slightly more effective at preventing invasive breast cancer (Fig. 74-18). However, neither reduced breast cancer-specific or all-cause mortality rates.¹⁶⁹

Both tamoxifen and raloxifene have estrogenic activity on the bone resulting in a decreased incidence of fractures, while only tamoxifen has estrogenic activity on the uterus and coagulation pathways. Therefore, tamoxifen use is associated with an increased risk of endometrial cancer (4 cases in 1,000 women, RR 2.13; 95% CI, 1.36 to 3.32) and thromboembolic events (4 cases in 1,000 women; RR 1.93; 95% CI, 1.41 to 2.64),¹⁶⁷ with a trend toward higher stroke rates and pulmonary embolism.¹⁷⁰ Despite these risks, quality-of-life measures (depression, anxiety, major psychosocial outcomes) show no differences in women receiving the drug versus placebo. However, an increase in vasomotor symptoms, gynecologic symptoms, and problems of sexual functioning was noted.^{171,172} As congenital anomalies have been associated with tamoxifen, women with childbearing potential must implement an effective contraceptive method. For women desiring a pregnancy, tamoxifen should be discontinued for at least 2 months prior to attempt at pregnancy.

Figure 74-18. Both tamoxifen and raloxifene when taken for 5 years in the National Surgical Adjuvant Breast and Bowel Project P-2 (STAR trial) were equally effective at reducing the risk of invasive breast cancer.

In postmenopausal women, studies show that aromatase inhibitors (AIs) are a reasonable alternative to tamoxifen and raloxifene. AIs suppress plasma estrogen levels by inhibition of aromatase, an enzyme that converts androgens to estrogens. Although AIs are commonly used for breast cancer treatment, they are not approved in the United States for breast cancer prevention at this time. Also, while both the USPSTF and the American Society of Clinical Oncology (ASCO) support the use of SERMs for both premenopausal and postmenopausal women, only ASCO considers the use of exemestane as a reasonable alternative to SERMs for postmenopausal women.¹⁷³ More recently, the International Breast Cancer Intervention Study (IBIS-II trial) showed that high-risk postmenopausal women who took the AI anastrozole had a 50% reduction in the number of invasive breast cancers and DCIS compared with placebo. The side effects of anastrozole include musculoskeletal problems, hypertension, vaginal dryness, and vasomotor symptoms.¹⁷⁴ AIs may also be associated with a loss of bone density.

The decision to proceed with endocrine therapy chemoprevention must be individualized. In general, the data support the use of endocrine therapy versus observation. For premenopausal and postmenopausal women, tamoxifen and raloxifene are both reasonable options. If a woman's primary concern is breast cancer prevention, then tamoxifen should be chosen. However, if there are risk factors for uterine cancer and or thromboembolic complications, raloxifene is a reasonable alternative. If a postmenopausal woman does not want to take a SERM, then an AI can be prescribed.

DUCTAL CARCINOMA IN SITU

DCIS is commonly defined as the proliferation of malignant epithelial cells within the mammary ductal system with no evidence of invasion into the surrounding stroma on routine light microscopic examination (Fig. 74-19). It is further categorized by its size, nuclear grade, presence and extent of comedo necrosis, and architectural pattern. Common histologic subtypes of DCIS include comedo, cribriform, micropapillary, papillary, and solid.¹⁷⁵ DCIS is designated as Tis (DCIS) by the TNM staging system and considered a stage 0 breast cancer.¹⁷⁶ The incidence of DCIS increases with age and is uncommon in women younger than 30 years. In women aged 50 to 64 years, the risk is as high as 88 per 100,000 women.¹⁷⁷ Among the breast cancers diagnosed in the United States, 25% are DCIS.¹⁷⁸ The risk of development of metastases and/or death in women with DCIS is rare (<1%).¹⁷⁹

Figure 74-19. Photomicrograph of ductal carcinoma in situ. The abnormal cells do not cross the ductal basement membrane. The necrotic debris in the center of the duct is responsible for the calcification visible on mammography.

Most patients with DCIS will present with no breast-related symptoms or findings on physical examination. More than 90% of all cases of DCIS are detected on imaging studies – commonly as microcalcifications on mammography.^{180,181} Prior to routine screening mammography, DCIS presented as a palpable mass, in association with nipple discharge, or as Paget disease.^{182,183} Although most patients with DCIS have microcalcifications of indeterminate morphology, patterns that are highly suggestive of DCIS include linear branching or segmental types of pleomorphic microcalcifications.¹⁸¹

Once an abnormal lesion is detected by diagnostic imaging, the diagnosis of DCIS is typically confirmed by breast biopsy. Of note, when DCIS is diagnosed initially by core biopsy, 15% to 20% of lesions will be upgraded to invasive cancer at the time of definitive resection. Large, high-grade DCIS lesions are more likely to have an invasive component.¹⁸⁴

5 Surgical options for the treatment of DCIS include breast-conserving surgery as a component of breast conservation therapy (BCT) (partial mastectomy and postoperative radiation therapy) or simple mastectomy. Although there is no randomized trial that has ever compared the treatment of DCIS by mastectomy with treatment by BCT, a large number of clinical studies have shown that the local recurrence rate of BCT is 10% to 15% after 10 years and that approximately half of the local recurrences are invasive carcinoma.¹⁸⁵⁻¹⁸⁹ Mastectomy is curative in 98% of patients with DCIS, regardless of the tumor grade or the size of the lesion.^{185,186} However, both surgical treatment options are associated with equivalent long-term survival as shown in both retrospective and prospective analyses.¹⁹⁰⁻¹⁹² Given that partial mastectomy is a much less invasive surgical procedure, BCT is typically recommended over mastectomy. Mastectomy should be performed if BCT is contraindicated, or based on patient preference. BCT is contraindicated with multicentric disease, extensive disease where resection would result in poor cosmesis, and in patients who cannot receive radiation therapy. For patients undergoing mastectomy, immediate breast reconstruction options should be considered.

BCT typically includes a partial mastectomy with negative surgical margins, followed by radiation therapy to eradicate any residual disease. Radiation therapy is often recommended, except in rare circumstances (see the section on Breast Cancer in the Elderly). Four prospective, randomized clinical trials – NSABP B-17^{188,189} (1998, 2001), EORTC 10853¹⁹³ (2006), United Kingdom¹⁹⁴ (2003), and the SweDCIS¹⁹⁵ (2008) have focused on the role of radiation therapy in the treatment of DCIS (Table 74-9). Despite differences in study design, the results are very similar, demonstrating a 50% to 60% reduction in local recurrence with surgical excision and radiation therapy compared to surgical excision alone. Furthermore, the results of NSABP B-17 confirm that the reduction in local recurrence persists through 12 years of follow-up. However, no survival benefit from radiation therapy was observed. Patients with comedo necrosis, uncertain margins, and/or those at highest risk for recurrence appear to benefit most from radiation therapy.¹⁹⁶ However, even in the most favorable subgroup (absent or slight comedo necrosis, clear margins), radiation therapy was associated with a reduction in the absolute incidence of breast recurrence by 7% at 8 years.

Given the risks, inconvenience, and cost associated with radiation therapy, attempts have been made to define a subgroup of patients with DCIS who may not require radiation therapy. The ECOG 5194 study investigated patients undergoing local excision alone in women with low-risk DCIS (low- to intermediate-grade DCIS lesions were <2.5 cm, and high-grade DCIS lesions were <1.0 cm). Margins were at least 3 mm and a postexcision mammogram was obtained for all patients to document the adequacy of surgical resection. Tamoxifen following excision was allowed but not required. At a median follow-up of 6.7 years, the local recurrence rate at 5 years was 6.1% (95% CI, 4.1% to 8.2%) for patients with low- to intermediate-grade DCIS (n = 565), and 15.3% (95% CI, 8.2% to 22.5%) for patients with high-grade DCIS (n = 105).¹⁹⁷ These findings suggest that local excision alone may be sufficient for select patients with low- to intermediate-grade DCIS. However, identifying these patients remains a challenge.

RESULTS

Table 74-9 Results of Randomized Trials of Radiotherapy in Ductal Carcinoma in Situ

Study	Patients (No.)	Median Follow-up (Mo)	IBTR (%)	
			E	RT
NSABP B-17 ^{181,182}	813	44	40	17
EORTC 10853 ¹⁸⁶	1,010	126	26	15
United Kingdom ¹⁸⁷	1,030	53	14	6
SweDCIS ¹⁸⁸	1,046	96 (mean)	27	12

DCIS, ductal carcinoma in situ; E, excision alone; EORTC, European Organization for Research and Treatment of Cancer; IBTR, ipsilateral breast tumor recurrence; NSABP, National Surgical Adjuvant Breast Project; RT, radiation therapy.

Other models that have attempted to predict the likelihood of local recurrence following excision alone in patients with DCIS include the Van Nuys Prognostic Index (VNPI)¹⁹⁸ and its updated version, the University of Southern California Van Nuys Prognostic Index (USC/VNPI).¹⁹⁹ Patients are classified into three groups on the basis of pathologic classification: (1) non-high-grade DCIS without comedo-type necrosis, (2) non-high-grade DCIS with comedo-type necrosis, and (3) high-grade DCIS with or

without comedo-type necrosis. The USC/VNPI score (range is 4 to 12) is then calculated on the basis of the pathologic classification score and points given for margins, tumor size, and the patient's age. The study's conclusion is that women with an overall low score (4, 5, 6) did not require radiation therapy. However, attempts to replicate and validate the USC/VNPI score in other data sets have had varying success^{200–202} and as such it is not commonly used.

More recently, gene expression analysis has been explored in an attempt to distinguish patients who may omit postexcision radiation therapy. The DCIS Recurrence Score is a multigene assay that was developed using tumors from 327 patients who participated in the ECOG5194 trial as described previously.²⁰³ The DCIS Recurrence Score is designed to stratify patients into three groups corresponding to the 10-year risk of developing ipsilateral DCIS or invasive breast cancer. Those with a low score (<39) had a risk of ipsilateral recurrence of 12% and 5%, respectively; intermediate score (39–54) had a risk of ipsilateral recurrence of 25% and 9%; and high score (>55) had a risk of ipsilateral recurrence of 27% and 19%. It must be noted that for some patients, a 12% risk of an ipsilateral recurrence at 10 years may not justify omission of radiation therapy. Furthermore, validation of this multigene assay is required prior to its implementation into clinical practice.

Axillary lymph node involvement in DCIS is rare, and sentinel lymph node biopsy is not indicated during breast-conserving surgery. In the NSABP B-17 and B-24 trials, the axillary recurrence rates, irrespective of treatment, were 0.83 and 0.36 per 1,000 patient-years of follow-up.²⁰⁴ If a patient is undergoing a mastectomy following core needle biopsy, SLN biopsy should be considered as it is possible that an occult invasive breast cancer will be identified, and SLNB is often not feasible after mastectomy. Of note, SLNB after a mastectomy has been explored through skin mapping. Radiocolloid with or without blue dye is injected superior to the mastectomy incision into the skin flap, with successful identification of a sentinel lymph node in 13 out of 20 patients (65% success rate).²⁰⁵ Our institution has had slightly higher success rates with the injection of both radiocolloid and blue dye.

After breast-conserving surgery, a postexcision mammogram should be obtained prior to the initiation of radiation therapy to ensure that there are no persistent residual suspicious calcifications. Treatment for DCIS after breast conserving surgery is not considered complete without adjuvant radiation therapy (see the section on Radiation Therapy).

There is no role for chemotherapy in DCIS. However, endocrine therapy is commonly recommended. Fifty percent to seventy-five percent of DCIS specimens express estrogen and progesterone receptors.^{206,207} In the United States, only tamoxifen has been approved to prevent breast cancer recurrences in women with DCIS. Currently, no data exist to support the use of AIs in this population. The benefit of tamoxifen therapy in decreasing local recurrence rates is supported by both a meta-analysis of two randomized trials and by NSABP B-24. The meta-analysis consists of 3,375 women and shows that tamoxifen after surgery for DCIS reduces recurrence of both ipsilateral DCIS (HR, 0.75; 95% CI, 0.61 to 0.92) and contralateral DCIS (HR, 0.50; 95% CI, 0.28 to 0.87) (Fig. 74-20). There is also a trend toward decreased ipsilateral invasive cancer (HR, 0.79; 95% CI, 0.62 to 1.01) and reduced contralateral invasive cancer (HR, 0.57; 95% CI, 0.39 to 0.83). The number needed to treat in order for tamoxifen to have a protective effect against all breast events was 15. However, there was no difference in all-cause mortality (RR, 1.11; 95% CI, 0.89 to 1.39).²⁰⁸ In a retrospective review of NSABP B-24, it was found that at 10 years of follow-up, patients (n = 732) with ER-positive DCIS treated with tamoxifen had significant decreases in any subsequent (invasive and/or noninvasive; ipsilateral and/or contralateral) breast cancer events compared with those who received placebo (HR, 0.58; 95% CI, 0.42 to 0.81; $p < 0.0015$).²⁰⁹

The NCCN Task Force guidelines for management of patients with DCIS who have not undergone bilateral mastectomies include consideration of tamoxifen for 5 years rather than observation, recognizing that although there is an improvement in recurrence rates, there is no proven survival benefit.²¹⁰ In women who have undergone bilateral mastectomies, the risks associated with tamoxifen use likely outweigh the benefits. Furthermore, tamoxifen is not typically recommended for patients with ER-negative DCIS.

EVALUATION OF THE PATIENT WITH BREAST CANCER

Breast cancer is a heterogeneous disease that can be characterized further on the basis of clinical and pathologic features. Further characterization and staging of breast cancer in patients with newly diagnosed breast cancer can facilitate definitive treatment. Pathologic, biologic, and anatomic characteristics are used in combination to predict prognosis and response to therapy.

Figure 74-20. Benefits of radiation therapy and tamoxifen in ductal carcinoma in situ. The cumulative incidence of breast cancer events in the ipsilateral and contralateral breasts for patients treated in the National Surgical Adjuvant Breast and Bowel Project B-17 and B-24 trials is shown. The reduction in recurrence is greatest for patients receiving radiotherapy and tamoxifen.

AJCC TNM Staging

The seventh edition of the AJCC TNM staging system for breast cancer is an internationally accepted system used to characterize the extent of disease, predict prognosis, and facilitate medical decision-making (Table 74-10).¹⁷⁶ In this system, breast cancer is classified on the basis of the primary tumor type (invasive or in situ) and size (T), the presence or absence of regional lymph node involvement (N), and the presence or absence of distant metastases (M).

Noninvasive breast cancers are noted as Tis and further classified into Tis (DCIS), Tis (LCIS), and Tis (Paget). T1 tumors are invasive cancers ≤ 20 mm; T2 tumors are > 20 mm but ≤ 50 mm; whereas T3 tumors are > 50 mm. T4 tumors are of any size with direct extension to the chest wall and/or the skin, resulting in nodules or ulcerations. Invasion of cancer into the dermis alone does not qualify as T4.

Lymph node classification criteria differ depending on whether the lymph nodes were clinically or pathologically assessed and as such are designated as cN or pN, respectively. When possible, pathologic classification is preferred. Regional lymph nodes are defined as those of the ipsilateral axilla, ipsilateral intramammary, internal mammary nodes, and supraclavicular nodes. Metastasis to any other lymph node, including cervical or to the contralateral axillary lymph node, is classified as distant disease (M1). In regard to the clinical classification of the regional lymph nodes, cN0 refers to no regional lymph node metastases. Mobile level I and II axillary lymph nodes containing metastases are considered cN1, whereas fixed or matted nodes are cN2. When metastases occur in the infraclavicular lymph nodes, ipsilateral internal mammary lymph nodes *and* axillary lymph nodes, or to the ipsilateral supraclavicular lymph nodes, it is classified as cN3.

In order to discuss the pathologic classification of regional lymph nodes, it is important to note that breast cancer metastases must be greater than 0.2 mm and exceed 200 cells in a single histologic lymph node cross-section to be considered clinically relevant. As such, pN0 refers to no regional lymph node metastases, pN1mi is used to describe micrometastases (> 0.2 mm or > 200 cells, but none > 2.0 mm), and pN1 is used to describe metastases in one to three lymph nodes and/or internal mammary nodes with metastases detected by SLN biopsy but not clinically detected. pN2 disease occurs when metastases are present in four to nine axillary lymph nodes or in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastases. pN3 disease includes metastases in 10 or more axillary lymph nodes, metastases to the infraclavicular (level III axillary) lymph nodes, in clinically detected ipsilateral internal mammary lymph nodes in the presence of one or more positive level I or II axillary lymph nodes, in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLN biopsy but not clinically detected, or in ipsilateral supraclavicular lymph nodes.

Distant metastasis (M1) is defined as detectable metastases as determined by classical clinical and radiographic means and/or histologically proven larger than 0.2 mm. When no clinical or radiographic evidence of distant metastases is present but deposits of molecularly or microscopically detected tumor cells are found in circulating blood, bone marrow, or other nonregional nodal tissue that is no larger than 0.2 mm in a patient with no symptoms of metastases, the designation used is cMO(i+).

The particular combination of the T, N, and M characteristics defines the overall breast cancer stage. Although the TNM staging system estimates predicted survival, it should not be used alone to dictate treatment.

Histologic Subtype and Tumor Grade

Most invasive breast cancers arise from epithelial elements and are categorized as carcinomas, consisting of several histologic subtypes. Based on the Surveillance, Epidemiology, and End Results (SEER) database of the National Cancer Institute between 1992 and 2001, estimated percentages of each histologic subtype of breast cancer in a series involving 135,157 women showed infiltrating ductal carcinoma (IDC) as the most common (76%), followed by invasive lobular (8%), ductal/lobular (7%), mucinous/colloid (2.4%), tubular (1.5%), medullary (1.2%), and then papillary (1%).²¹¹

Infiltrating ductal carcinoma is the most common type of invasive breast cancer. On gross pathologic evaluation, these lesions are typically firm, gray–white, gritty masses. Cytologic features of these cells range from low grade to highly malignant. Microscopically, these cancers are characterized by cords and nests of tumors cells with varying amounts of gland formation. As these cancer cells infiltrate the breast parenchyma, they induce a fibrous response, resulting in their characteristic irregular, stellate shape. Often, IDC is associated with a variable amount of DCIS.

STAGING

Table 74-10 Tumor, Node, Metastasis (TNM) Classification for Breast Cancer Staging

TNM Definitions			
Primary Tumor			
Tx	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ, ductal or lobular or Paget disease of the nipple with no tumor		
T1	Tumor 2 cm or less in greatest dimension		
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension		
T3	Tumor more than 5 cm in greatest dimension		
T4	Tumor of any size with direct extension to the chest wall (not including pectoralis muscle), skin edema, skin ulceration, satellite skin nodules, or inflammatory carcinoma		
Regional Lymph Nodes (Pathologic)			
Nx	Nodes cannot be assessed		
N0	No regional node metastases histologically, no additional examination for isolated tumor cells (ITCs)		
N1	Metastasis to one to three axillary nodes or in internal mammary (IM) nodes with microscopic disease detected by sentinel node biopsy, which is not clinically apparent		
N2	Metastases in four to nine axillary nodes or in clinically apparent IM nodes in the absence of axillary node metastasis		
N3	Metastases in 10 or more axillary nodes, or in infraclavicular nodes, or in IM nodes in the presence of one or more positive axillary nodes; or in more than three axillary nodes with IM metastases, or in supraclavicular nodes		
Distant Metastases			
Mx	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
Stage Grouping			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T0	N1	M0
	T1	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
	T3	N2	M0
Stage IIIA	T0	N2	M0
	T1	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
	Any T	N3	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any T	M1

The AJCC Staging System for Breast Cancer.

Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springer.com

Infiltrating lobular carcinomas (ILCs) are the second most common type of breast cancer. The incidence rate of lobular carcinoma is rising faster than the rate of ductal carcinoma in the United States. Furthermore, postmenopausal hormone therapy use may be more strongly associated with lobular carcinoma than with ductal carcinoma. Although some ILCs may appear similar to IDC macroscopically, others may not show a mass lesion with the excised tissue appearing normal or having only a slightly firm consistency. As such, the microscopic size of ILC may be much greater than what is measured grossly. Unlike IDC, ILC induces only a minimal fibrous reaction. Microscopically, these tumors are characterized by small cells that insidiously infiltrate the mammary stroma and adipose tissue individually and in a single file pattern, often growing in a target-like configuration around normal breast ducts. LCIS or DCIS may be present with ILC. There is a higher frequency of bilateral and multicentric disease with ILC than with IDC.^{212,213} Infiltrating lobular carcinomas are more common in older women and are typically larger but more differentiated than IDC. Infiltrating lobular carcinomas are almost always ER-positive. The prognosis for ILC and IDC appears to be similar; however, recent reports suggest that the short-term prognosis for ILC may be more favorable.^{214,215} Infiltrating lobular carcinomas tend to metastasize later than IDC and spread to unusual locations such as the peritoneum, meninges, and the gastrointestinal tract.²¹⁶ Furthermore, lobular breast cancers have been observed in

families that carry germline mutations in *CDH1*, the gene that encodes for the E-cadherin protein. The lack of E-cadherin can be used to distinguish ILC from IDC.^{217,218}

Mucinous (colloid) carcinoma is a less common histologic subtype that is more common in older patients. On gross examination, these tumors have a soft gelatinous appearance and tend to be well circumscribed. Microscopically, they are characterized by nests of tumor cells, with uniform and low-grade nuclei, dispersed in large pools of extracellular mucus. These lesions have a favorable prognosis.^{219,220} Another histologic subtype with favorable prognosis is tubular carcinoma, which is characterized by the presence of well-formed tubular or glandular structures infiltrating the stroma. The tumor cells are low grade and are often associated with low-grade DCIS. Metastatic disease is rare with tubular carcinoma.²²¹

Medullary carcinomas are well-circumscribed, soft, tan masses with areas of hemorrhage and necrosis. Microscopically, the tumor cells are poorly differentiated, grow in a syncytial pattern, and have an intense lymphoplasmacytic infiltrate.²²² These cancers occur more frequently in younger patients and are more frequent in women with *BRCA1* mutations, although the majority of breast cancers in patients with *BRCA1* mutation are not medullary.²²³ Despite their aggressive histologic appearance, medullary carcinomas are associated with a more favorable prognosis than IDC.^{224,225}

Other breast cancer subtypes include macropapillary carcinomas that are highly aggressive and have a tendency for lymph node metastasis even when small in size.²²⁶ Also likely associated with a worse prognosis, metaplastic carcinomas are well-circumscribed tumors that contain various combinations of poorly differentiated ductal adenocarcinoma, mesenchymal (sarcomatous), and other epithelial (e.g., squamous cell) components.²²⁷ When the squamous cell component predominates, the tumors tend to be more aggressive and are frequently refractory to treatment when compared with IDC.^{228,229} Unlike IDC, metaplastic breast cancers tend to have fewer T1 tumors, more node-negative tumors, more poorly differentiated or undifferentiated tumors, and have fewer ER-positive tumors.²²⁷ Metaplastic breast cancers are treated similarly to other invasive breast cancers.^{230–232}

The grade of a breast cancer is determined by a combination of the architectural and cytologic features, usually assessed by utilizing the Ellston–Ellis modification of the Scarff–Bloom–Richardson scoring system. This system is based on three parameters including tubule formation, nuclear pleomorphism, and mitotic activity. Each category is assigned a score of 1 to 3 and then a summation score of 3 to 9. The lowest possible score is 3 with scores of 3 to 5 defined as grade 1, 6 or 7 as grade 2, and 8 or 9 as grade 3. Cells that infiltrate the stroma as solid nests of glands and where the nuclei are relatively uniform with little or no evidence of mitotic activity are referred to as well differentiated or grade 1 tumors. When the tumor cells infiltrate as solid nests with some glandular differentiation and nuclear pleomorphism is present, the tumor is categorized as grade 2 or moderately differentiated. In addition, the mitotic activity is moderate. In poorly differentiated or grade 3 tumors, solid nests of neoplastic cells without evidence of gland formation are present. In addition, there is marked nuclear atypia and high mitotic activity.²³³

Biomarker Profile (ER, PR, HER2)

As targeted therapies exist against the estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER2), these biomarkers have significant treatment implications. As such, when an invasive breast cancer is diagnosed, expression of these biomarkers is determined. Using immunohistochemistry and image analysis, ER and PR are considered positive if 10% of cells or greater stain positive. The Allred score is another method to quantify ER and PR expression. The Allred score integrates the percentage of cells that stain positive with the intensity of staining to give a score of 0–8.²³⁴ The goal of the Allred score is to quantify ER expression on the basis of the likelihood that a patient with breast cancer will respond to endocrine therapy. One of the benefits of the Allred score is that by integrating both the percentage and intensity of staining, patients with <10% staining may be identified who benefit from endocrine therapy.²³⁵ The receptor tyrosine kinase protein HER2 is a member of the epidermal growth factor receptor family and its amplification or overexpression has been shown to contribute to breast cancer development and progression. HER2 can now be targeted using monoclonal antibodies and small molecule inhibitors. Using immunohistochemistry and image analysis, HER2 is scored 0, 1+, 2+, and 3+. Positivity is noted as 3+, whereas scores of 0 and 1+ are considered negative. A score of 2+ is considered indeterminate and further testing for gene amplification can be performed using either FISH (fluorescence in situ hybridization) or CISH (chromogenic in situ hybridization). The HER2 FISH assay is based on the gene copy number and the ratio between the number of HER2 and chromosome enumeration probe 17 (CEP17) sequences, with

positivity defined as a HER2/CEP17 ratio of ≥ 2.0 . Positivity is also defined as HER2 copy number ≥ 6.0 signals/cell even if the HER2/CEP17 ratio is < 2.0 .²³⁶ Alternatively, a more cost-effective and comparable method to FISH testing is the HER2 CISH assay.^{237,238}

An emerging biomarker is the Ki-67 index. The Ki-67 antigen is present in all phases of the cell cycle except for the G0/resting phase and reflects of the proliferative potential of a breast cancer. Ki-67 is determined by IHC and noted as a percentage, where $< 10\%$ is considered a low proliferative index, 10% to 20% is considered borderline, and $> 20\%$ is considered high. The Ki-67 index can also be used to measure the response to endocrine therapy.

Molecular Subtyping

Recent advances in molecular biology, including the development of sophisticated techniques for gene expression profiling, have established a new taxonomy of breast cancer, defining molecular subtypes of breast cancer. This new taxonomy has had a profound impact on the clinical management of breast cancer, as the molecular subtypes differ markedly in prognosis and response to therapy. As gene expression profiling is not routinely performed on clinical specimens, molecular subtypes have been approximated on the basis of expression of the ER, PR, HER2 expression, and other biomarkers. Commonly defined subtypes include luminal A (ER+, PR+, HER2–, Ki-67 $< 14\%$), luminal B (ER+ and or PR+, HER2+/-, Ki-67 $\geq 14\%$), HER2 (ER and PR–, HER2+), and basal-like (ER, PR, and HER–).^{239–241} Luminal A and B subtypes have ER expression; however, the former group has a much better overall survival.²⁴² Luminal B HER2+ and HER2 subtypes benefit from targeted therapies against HER2. Furthermore, both HER2 and basal-like breast cancers are known to have higher initial responses to anthracycline-based chemotherapy than the luminal subtypes but are associated with a decreased disease-free survival.²⁴³

Breast MRI

Although there are no data from prospective randomized trials demonstrating improved outcomes with the addition of MRI to the diagnostic evaluation of newly diagnosed breast cancers, the NCCN guidelines suggest that diagnostic MRI should be considered in patients with newly diagnosed breast cancer (1) when the clinical extent of disease appears larger than what is observed on mammography, (2) when there is concern about pectoralis muscle involvement, (3) when there is no evidence of a breast primary in the presence of axillary lymph node metastases, (4) when there is no disease identified on physical examination or mammography in the presence of PDB, (5) in women at very high risk for contralateral breast cancers such as those with *BRCA1/2* mutations, and (6) to help determine the extent of disease prior to treatment. Of note, MRI is associated with a high false-positive rate, and many MRI-detected abnormalities will need to be biopsied in order to meaningfully interpret the results of the MRI.

Table 74-11 Approach To the Axillary Nodes

Finding	Approach
Clinically negative	Sentinel lymph node biopsy
Radiographically suspicious	Fine-needle aspiration (image guided) If no metastatic disease identified, then sentinel lymph node biopsy If metastatic disease is identified, consideration for axillary lymph node dissection
Clinically suspicious	Fine-needle aspiration (image or hand guided) Follow-up management as for radiographically suspicious

Sentinel Lymph Node Biopsy

Breast cancer spread to ipsilateral axillary lymph nodes is common, occurring in 15% to 30% of patients. The presence of axillary lymph node metastases has important prognostic implications and can impact medical, surgical, and radiation oncology decision-making. However, axillary lymph node dissection (ALND) has significant risks, and the therapeutic impact of axillary surgery remains to be clearly defined.^{244–246} Currently, SLNB is the procedure of choice for staging of the axilla in breast

cancer. Axillary ultrasound has also been used and can facilitate evaluation of patients with an equivocal physical examination (Table 74-11).

6 The SLN hypothesis predicts that breast cancers metastasize to one or a few lymph nodes before involving other lymph nodes in the corresponding lymph node basin. Prospective studies have confirmed this hypothesis, demonstrating that the pathology of the SLN accurately predicts the pathology of the corresponding axillary lymph node basin (Table 74-12). SLNB has significantly fewer complications than ALND, with the risk of lymphedema being significantly lower (2% after SLNB versus 13% after ALND at 12 months).²⁴⁷

The SLNB procedure begins with localization of the SLN through injection of radioactive colloid and/or blue dye. Given that the combined use of both tracers appears to be complementary and that failed SLN identification is minimized when both tracers are used, this is our recommended approach. A systematic review by an expert panel convened by ASCO concluded that the use of both blue dye and radioactive colloid was associated with a trend toward a lower false-negative rate.²⁴⁸

Prior to surgery, radioactive technetium sulfur colloid is injected peritumorally, intradermally, or into the subareolar plexus. Lymphoscintigraphy can be performed to identify areas of increased radioactivity. Alternatively, a handheld gamma probe can be used to survey the axilla and identify hot spots. The patient is then brought to the operating room and positioned with the ipsilateral arm abducted up to 90 degrees. The breast, anterior chest wall, and axilla are prepped and draped in the usual standard sterile fashion. Five milliliters of blue dye (isosulfan or methylene blue dye) is injected around the tumor periphery, at the palpable edge of the biopsy cavity, or into the subareolar plexus. Blue dye should not be injected directly into the tumor itself as the lymphatics may be occluded by tumor. Likewise, blue dye should not be injected into the seroma cavity following breast surgery as the seroma cavity may not have sufficient lymphatic drainage. For these reasons, we typically inject into the subareolar plexus. Breast massage is performed for 5 minutes to dilate the breast lymphatics and facilitate lymphatic drainage.

Isosulfan blue can be used for SLNB; however, anaphylaxis requiring resuscitation can occur in 0.7% to 1.1% of cases.^{249,250} Alternatively, methylene blue can be used. The risks associated with methylene blue include skin necrosis if injected intradermally, pain secondary to caustic reaction, and pulmonary edema.²⁵¹⁻²⁵³ These risks can be minimized by diluting the methylene blue, with common dilutions ranging from 2:3 (2 mL of methylene blue mixed with 3 mL of saline, injecting 5 mL total) to 1:4 (1 mL of methylene blue mixed with 4 mL of saline, injecting 5 mL total). In patients taking serotonergic psychiatric medications, methylene blue should be used with caution as the dye can prevent the action of monoamine oxidase A, resulting in toxic levels of serotonin or serotonin syndrome. This is characterized by mental status changes, muscle twitching, excessive sweating, shivering, diarrhea, trouble with coordination, and/or fever.²⁵⁴

Using a handheld gamma probe, the axilla is systematically surveyed and the skin is marked at the location of the hottest spot. A small incision is then made below the hair-bearing area of the axilla and carried down through the subcutaneous tissue. The clavipectoral fascia is incised with care to visually identify any blue lymphatics. The blue lymphatics are then followed toward the axilla to identify the sentinel lymph node(s). Successful SLN identification by blue dye is defined as the identification of any blue node or non-blue node with a blue afferent lymphatic. These lymph nodes are also evaluated with the gamma probe and the associated counts are recorded. The dissection is continued until all lymph nodes associated with a blue afferent lymphatic are removed and any remaining lymph nodes have less than 10% radioactivity compared to the most radioactive lymph node.²⁵⁹⁻²⁶¹ This often results in more than one SLN being identified and removed. Finally, palpation of the axilla is performed and any suspicious lymph nodes are also removed as gross tumor involvement can interfere with uptake of both radioactive colloid and blue dye. In the case of gross tumor involvement, the radioactive colloid and blue dye may be diverted to a lymph node other than the true SLN, giving rise to a false-negative result if palpation of the axilla and removal of suspicious lymph nodes is not performed.^{262,263} Once all SLNs have been identified and removed, the clavipectoral fascia is reapproximated and the skin is closed in two layers.

RESULTS

TREATMENT OF THE PATIENT WITH BREAST CANCER

Breast cancer is currently treated with a multidisciplinary approach. Most patients benefit from a combination of therapies that may include surgery, medical therapy, and radiation therapy. This multidisciplinary approach has resulted in a significant reduction in breast cancer mortality.²⁶⁴ One important consideration is optimal coordination of surgery with the other treatment modalities. In the discussion below we will first provide an overview of how the different treatment modalities are coordinated in early stage, locally advanced, and metastatic breast cancer. After this overview, surgery, medical therapy, and radiation therapy will be discussed in more detail.

Overview

7 Most patients with newly diagnosed breast cancer have no evidence of metastatic disease and are diagnosed with *early stage* breast cancer. This includes patients with clinical stage I (T1N0), IIA (T1N1 or T2N0), or IIB (T2N1) disease. Local regional management often consists of BCT (partial mastectomy with radiation therapy) or mastectomy, noting that the choice in locoregional management does not typically impact the recommendation for adjuvant medical therapy. For patients with clinical T1N0 disease, surgery is typically the first treatment modality. For patients with clinical T2N0 or T2N1 disease, neoadjuvant chemotherapy or endocrine therapy is often the first treatment modality. The goal of neoadjuvant therapy is to shrink the primary breast cancer prior to surgery, facilitating BCT. For patients with a clinically suspicious axilla, an ultrasound-guided FNA may be helpful to determine whether there is metastatic spread to the axilla. If the FNA is negative, then the patient should undergo a SLNB at the time of surgery. For patients with a clinically negative axilla, a SLNB should be planned at the time of surgery with a decision about further management of the axilla, if any, pending the results of the SLNB. The decision to recommend chemotherapy for patients with early breast cancer is primarily dependent on tumor characteristics but also integrates the patient's overall health status and personal preference. Adjuvant chemotherapy is typically recommended when high-risk features are present such as high-grade tumor, large tumor size (≥ 1.0 cm), unfavorable biomarker profile, or lymph node involvement. In addition, an Oncotype DX can be obtained in patients with ER⁺/HER2-negative breast cancers and negative lymph nodes. A score of ≥ 31 often suggests that adjuvant chemotherapy will be beneficial. For patients with breast cancers that are hormone receptor-positive, endocrine therapy is typically recommended postoperatively. If adjuvant chemotherapy is recommended, then endocrine therapy is given after completion of chemotherapy. For patients with TNBC, adjuvant chemotherapy is commonly given if the tumor size is ≥ 0.5 cm. Patients who have HER2-positive breast cancers that are ≥ 1.0 cm are treated with adjuvant chemotherapy plus HER2-directed therapy. The management of HER2-positive breast cancers that are < 1.0 cm is controversial and should be decided by the patient and her provider after a discussion of the risks and benefits of treatment. Adjuvant radiation therapy is typically recommended for all patients who are treated with BCT and a subset of patients who are treated with mastectomy (see the section on Radiation Therapy).

Patients with *locally advanced disease* (clinical stage IIB (T3N0) or stage IIIA-IIIC (T1-T3N2 disease, T4 disease)) are at a higher risk for recurrence and distant metastases, and neoadjuvant and/or adjuvant chemotherapy and radiation therapy are typically recommended (Fig. 74-21). Benefits of neoadjuvant chemotherapy in this clinical context include the ability to treat any potential systemic disease immediately and the ability to directly assess the response to treatment by physical examination and imaging, allowing for suboptimal regimens to be discontinued and other regimens to be prescribed. In patients with hormone receptor-positive disease, neoadjuvant chemotherapy is associated with a higher response rate in a shorter period of time than endocrine therapy. Endocrine therapy in the neoadjuvant setting is often reserved for postmenopausal women who have contraindications to chemotherapy. For

patients with HER2-positive breast cancer, HER2-directed therapy such as trastuzumab is often given with pertuzumab along with chemotherapy. If a patient has a limited response or cannot tolerate the neoadjuvant regimen, she should proceed with surgery. Even if patients have an excellent clinical response, they should undergo surgery to remove the area of involvement. Although BCT is an option for patients with locally advanced breast cancer (LABC) who have a significant clinical response to neoadjuvant chemotherapy, mastectomy is typically recommended for those who initially present with breast cancers that are greater than 5 cm.

Approximately 5% of patients with newly diagnosed breast cancer will present with stage IV disease, and up to 30% of patients who present with early stage breast cancer at diagnosis will develop distant metastatic disease.²⁶⁵ The approach to patients with metastatic breast cancer is focused on prolonging survival and improving quality of life by minimizing cancer- related symptoms. As such, the treatment plans for these patients are highly individualized.

Figure 74-21. Locally advanced breast cancer. The breast is lifted and the upper half is bulging because of the large tumor. Distortion in the inferolateral contour is evident. The medial skin changes are caused by dermal tumor satellites.

TREATMENT

Table 74-13 Recommendations for Adjuvant Therapy

Patient Group	Recommended Treatment
Node Negative, Low Risk	
Tumor <0.5 cm	No treatment or endocrine therapy if ER+
Special histologic types	
1–2 cm, grade 1, ER+	
Node Negative, Higher Risk	
ER+	Endocrine therapy OR chemotherapy + endocrine therapy
ER–	Chemotherapy
Any HER2+	Add trastuzumab to chemotherapy
Node Positive	
ER+	
Premenopausal	Chemotherapy + endocrine therapy
Postmenopausal	Chemotherapy + endocrine therapy OR endocrine therapy alone
ER–	Chemotherapy
Any HER2+	Add trastuzumab to chemotherapy

ER+, estrogen receptor positive; ER–, estrogen receptor negative.

For patients with hormone receptor-positive, HER2- negative disease, the preference is for endocrine therapy alone. However, for patients with rapidly progressing disease, endocrine-resistant disease, or a large tumor burden involving visceral organs, chemotherapy should be considered.^{266,267} For patients with HER2+ disease, HER2-directed therapies should be administered along with chemotherapy. For patients with TNBCs, chemotherapy is the only option for the treatment of metastatic disease.

When chemotherapy is indicated, the preference is for sequential single agent therapy, which includes

taxanes and anthracyclines. Other options, especially for patients with bone-predominant ER+ metastatic disease who have failed two trials of endocrine therapy, include capecitabine, which is derived from the antimetabolite fluorouracil. Capecitabine also may be indicated for metastatic disease to the brain as it appears to cross the blood–brain barrier.^{268–270} Other agents include eribulin, gemcitabine, ixabepilone, etoposide, and platinum agents.

Although combination chemotherapy conveys a higher risk of toxicity, its use is indicated when tumor burden is large or when patients have significant symptomatic disease. This includes anthracycline-containing regimens, non–anthracycline taxane-based regimens, and combination regimens incorporating platinum salts. It is important to note that no prospective study has shown that combination chemotherapy improves overall survival compared with single agent sequential chemotherapy.

For women with metastatic breast cancer, data exist that extending chemotherapy duration is associated with improved progression-free and overall survival. However, prolonged chemotherapy can be associated with more serious toxicities such as neutropenia and neuropathy.^{271,272} As such, an individualized approach should be undertaken weighing tumor response against side effects. During treatment of metastatic disease, the patient needs to be monitored for treatment failure, which includes clinical deterioration during treatment, evidence of new metastatic disease, and increasing size of previously documented metastatic lesions.

The recommendations for adjuvant therapy are summarized in [Table 74-13](#).

Surgical Therapy

Partial Mastectomy

BCT consists of breast-conserving surgery (partial mastectomy) followed by radiation therapy ([Fig. 74-22](#)). The use of BCT is supported by six prospective randomized clinical trials demonstrating that partial mastectomy plus radiation therapy offers equivalent survival to mastectomy with a low rate of local recurrence ([Table 74-14](#)).^{273–281} The local recurrence rate with BCT is 5% to 22% versus 4% to 14% with mastectomy. Of note, most recurrences after mastectomy occur within the first 3 years, but recurrences after BCT tend to occur later.^{282–284} Factors that increase local recurrence rate following partial mastectomy include young age, lymph node involvement, ER– disease, and absence of radiation therapy.²⁸⁵ The American College of Surgeons, the American College of Radiology, the College of American Pathologists, and the Society of Surgical Oncology have developed consensus standards of care for BCT.²⁸⁶ Most patients can be offered BCT except for those with (1) multicentric disease, (2) diffuse suspicious microcalcifications on mammography, (3) a history of radiation therapy that includes a portion of the affected breast such that when combined with the current proposed treatment would result in an excessively high total radiation dose to the chest wall, (4) pregnancy (although if in the third trimester, partial mastectomy can be performed with planned breast irradiation deferred postpartum), (5) IBC, and (6) persistently positive margins after multiple attempts at breast-conserving surgery ([Table 74-15](#)).

Figure 74-22. Cosmetic outcome after breast-conserving therapy with radiation. **A:** Excellent cosmetic outcome. The treated breast (left) is identical to the untreated breast. **B:** Fair cosmetic outcome. Significant shrinkage and loss of ptosis is evident in the treated right breast.

Table 74-14 Survival in Prospective Randomized Trials Comparing Breast-Conserving Therapy with Mastectomy

8, 9 The operative approach for a partial mastectomy is very similar to an excisional biopsy and is sometimes referred to as a wide excision, lumpectomy, or segmental mastectomy. The considerations for placement of the incision are similar to those for excisional biopsy; however, it is best to keep the incision within the boundaries of a potential mastectomy incision, and the incision should be made directly over the lesion rather than at the wire insertion site to minimize tunneling. As negative margins are associated with lower rates of recurrence, many techniques have been developed to ensure negative margins at the time of the initial surgery. One common technique is to remove the breast cancer with surrounding normal tissue and then obtain additional shave margins. Each shave margin is labeled and oriented in relationship to the primary cancer.²⁹³⁻²⁹⁸ In a randomized controlled trial, it was found that cavity shaving at the time of partial mastectomy halved the rates of positive margins (34% vs. 19%, $P = 0.01$) and reexcision (21% vs. 10%, $P = 0.02$).²⁹⁹ Approaches to evaluate intraoperative margin status include frozen section, cytologic touch prep analysis, and intraoperative ultrasound. However, no method has proven superior and there is no established standard of care. In patients undergoing breast-conserving surgery, it is important to discuss the potential need for reexcision. A histologically positive margin is defined as a margin that has tumor present at the inked margin. Patients with a positive margin have at least a twofold increase in ipsilateral local breast cancer recurrence. As such, controversy has centered on the optimal amount of normal tissue that should be excised around the cancer to minimize local recurrence risk. A recent multidisciplinary consensus panel supports the use of “tumor at ink” as the criteria for positive margin/reexcision based on a meta-analysis that included 33 studies with 28,162 patients and 1,506 ipsilateral recurrences.³⁰⁰ Like most other institutions, we have adopted this new definition of a positive margin for invasive breast cancers to guide decisions about reexcision. However, given the concern for gaps between lesions or skip lesions in DCIS, we continue to define a negative margin for this pathology as ≥ 2 mm, understanding that this practice may evolve pending more study results.

INDICATIONS/CONTRAINDICATIONS

Table 74-15 Contraindications to Breast-Conserving Therapy in Invasive Carcinoma

Absolute Contraindications

- Two or more primary tumors in separate quadrants of the breast
- Persistent positive margins after reasonable surgical attempts
- Pregnancy is an absolute contraindication to the use of breast irradiation. When cancer is diagnosed in the third trimester, it may be possible to perform breast-conserving surgery and treat the patient with irradiation after delivery
- A history of prior therapeutic irradiation to the breast region that would result in retreatment to an excessively high radiation dose
- Diffuse malignant-appearing microcalcifications

Relative Contraindications

- A history of scleroderma or active systemic lupus erythematosus
- Large tumor in a small breast that would result in cosmesis unacceptable to the patient. In this circumstance, preoperative chemotherapy should be considered.
- Very large or pendulous breasts if reproducibility of patient setup and adequate dose homogeneity cannot be ensured

Axillary Lymph Node Dissection

Until recently, ALND was performed in all patients with newly diagnosed breast cancer to facilitate staging, medical decision-making, and to minimize locoregional recurrence. More recently, SLNB has replaced ALND for axillary staging, and the therapeutic impact of ALND may be limited to specific subsets of patients with breast cancer. In the American College of Surgeons Oncology Group Z0011 trial, eligible patients had T1-T2 invasive breast cancers, no palpable adenopathy, and 1 to 2 SLNs containing metastases identified by frozen section, touch preparation, or H&E staining. Patients were randomized to undergo ALND or no further axillary treatment. Systemic therapy was at the discretion of the treating physician. Patients ineligible for the trial included those with matted lymph nodes, ≥ 3 positive nodes, gross extranodal disease, and those treated with neoadjuvant therapy.³⁰¹ After 6 years of follow-up, SLNB alone was not inferior to ALND in patients with limited sentinel lymph node involvement treated with BCT. Of note, these findings have been compared with those of the NSABP B04 trial that was conducted over a decade ago, which randomized women with clinically negative nodes to treatment with radical mastectomy, total mastectomy plus axillary radiation, or total mastectomy with delayed ALND if nodal recurrences were observed. No statistically significant survival differences were observed between any of the groups initially or at any of the analyses up to 25 years of follow-up.²⁴⁴ These studies suggest that for contemporary women, ALND may not provide a survival benefit in patients who are clinically node-negative. Currently, ALND is limited to patients with positive sentinel lymph nodes who do not meet Z0011 criteria, those with a contraindication to SLNB such as those with clinically palpable pathologic lymph nodes and patients with IBC.

Figure 74-23. A: Anatomical landmarks of the axilla. The boundaries of the axillary lymph node dissection are the axillary vein superiorly, the latissimus dorsi and thoracodorsal bundle laterally, and the serratus anterior muscle and long thoracic nerve medially. B: Lymphatic drainage of the breast. During an axillary lymph node dissection, level 1 and 2 lymph nodes are removed.

The boundaries of an ALND are the axillary vein superiorly, the serratus anterior muscle and long thoracic nerve medially, and the latissimus dorsi muscle and thoracodorsal nerve laterally. Contemporary axillary dissection in breast cancer involves removal of the level 1 and 2 lymph nodes (Fig. 74-23).³⁰² Level 3 nodes are palpated and only in the presence of gross disease is dissection performed, as removal of these nodes greatly increases the risk of lymphedema and is rarely (<1%) involved in the absence of level 1 and 2 diseases.^{303,304} Typically, a yield of ≥ 10 axillary lymph nodes is achieved with ALND.

The procedure is performed under a general anesthetic that does not include a muscle relaxant as identification of the long thoracic and thoracodorsal nerves is critical to the dissection. Preoperative antibiotics and deep venous thrombosis prophylaxis with sequential compression devices are employed. The patient is placed in the supine position with the ipsilateral arm abducted ≤ 90 degrees. Use of a stockinette allows for mobilization of the arm during dissection. If the ALND is performed through a mastectomy incision (modified radical mastectomy), no additional incisions are required. Also, for partial mastectomies performed in the upper outer quadrant, the partial mastectomy incision can be extended to the axilla. For palpable nodes that are close to, or have eroded the skin, it is important to take the overlying skin during the dissection.

For an ALND performed during a partial mastectomy or as a separate procedure, a curvilinear skin incision is made 1 to 2 cm below the hair-bearing area of the axilla, following Langer's lines from the border of the pectoralis major muscle to the latissimus dorsi muscle. Although flaps can be developed superiorly, inferiorly, laterally, and medially, most surgeons find that this is not necessary. Once the skin incision is made, the lateral edge of the pectoralis major muscle (PM) is palpated and the PM fascia is then opened with electrocautery. The lateral edge of the PM is then retracted medially to expose the pectoralis minor muscle (PMi), with care to avoid injury to the medial pectoral nerve, which innervates both the PM and the PMi. The tissue at the border of the PMi is then incised with care to avoid injury to the axillary vein or brachial plexus superiorly. If the arm is in a stockinette, it should be flexed medially and anteriorly to relax the PMi. The PM and PMi are then retracted and using blunt dissection, the axillary vein at the medial extent of the dissection can be identified. Further blunt dissection can be performed just below the medial aspect of the axillary vein and just lateral to the chest wall to identify the long thoracic nerve. The long thoracic nerve can also be palpated along the chest wall and once it is identified, the nerve is dissected free of surrounding tissue inferiorly to the insertion. To avoid injury, the fascial layer on the serratus anterior muscle that holds the nerve in place should not be opened. Attention is now turned to identification of the thoracodorsal nerve. Dissection is initiated midaxilla just inferior to the axillary vein. Anterior to the bundle is often the thoracoepigastric vein, which is a large superficial venous tributary arising from the axillary vein. Although the thoracoepigastric vein may

need to be transected to allow for completion of the dissection, it is important to first identify the thoracodorsal nerve. The axillary fat pad/contents can then be dissected away from the thoracodorsal bundle using blunt dissection from superiorly to inferiorly with a long fine tonsil clamp. Once the long thoracic and thoracodorsal nerves are identified and dissected free of surrounding tissue, the axillary contents can be mobilized and removed. Of note, there are usually three to five intercostobrachial nerves that supply sensation to the medial–posterior aspect of the arm and run medial to lateral in the field of dissection. An attempt should be made to spare these nerves but only if they do not directly interfere with the dissection. The axillary contents are retracted inferiorly, and using electrocautery or sharp dissection, it is freed from the teres major posteriorly. The axillary contents are then sent en bloc to the pathologist. A single 15 or 19 French round Blake drain can be placed above or below the bra line. However, some surgeons do not place drains for ALNDs, as in the absence of an associated mastectomy, the drainage is often scant. If a drain is placed, it is removed when drainage is less than 30 mL per 24 hours. No antibiotic prophylaxis is necessary.

The approach to ALND described above is a medial to lateral approach with the long thoracic nerve, axillary vein, and thoracodorsal nerve identified in sequence. Alternatively, one can approach the dissection through a lateral to medial approach. With this method, once the clavipectoral fascia is incised to enter the true axilla, the anterior surface of the latissimus dorsi is identified at the lateral extent of the axillary dissection. The clavipectoral fascia is then incised along the superior and medial aspects of the axilla. Dissection is then performed to first identify the thoracodorsal nerve, then the axillary vein superiorly, and then the long thoracic nerve medially. Once all the nerves and vascular structures are identified, the axillary contents are mobilized and removed.

Complications from ALND include motor and/or sensory nerve injury. Injury to the long thoracic nerve may result in winged scapula, whereas injury to the thoracodorsal nerve leads to weakness of internal rotation and extension, characterized by the functional inability to hold a book under the arm. Other risks include seroma formation, infection, and lymphedema.^{305–307} The risk of lymphedema is lifelong and is as high as 30%.

Simple Mastectomy

A mastectomy is performed for patients with breast cancer who are not candidates for BCT or for patients who prefer a mastectomy. For women at high risk for the development of breast cancer, it can be performed as a prophylactic procedure. The goal of mastectomy is complete removal of the breast tissue while preserving muscle function and viable skin flaps for primary closure. Preoperatively, the patient is examined in the holding area, where the breast is marked and the correct site of surgery is confirmed. An intravenous antibiotic that covers skin flora, such as cefazolin, given before skin incision has been shown to significantly decrease the risk of infection in patients undergoing mastectomy (RR 0.60; 95% CI, 0.450 to 0.81).³⁰⁸ The patient is then placed in the supine position with the arms abducted up to 90 degrees with padding placed beneath the arms and wrist to avoid brachial nerve and radial nerve injury. The skin is then cleansed with a preparation of chlorhexidine gluconate/isopropyl alcohol or Betadine solution and the patient is draped in a sterile fashion. The most common skin incision used is an elliptical incision in the horizontal (Stewart Incision) or diagonal plane (Orr Incision), although historically a vertical plane incision for high lying or infraclavicular lesions has also been used (Fig. 74-24). The medial border of this incision is 2 cm from the sternal edge and the lateral border is at the midaxillary line. The elliptical incision should include the skin directly over the tumor, especially if the tumor is superficial. Once the incision is made, a superior skin flap is developed in the relatively avascular plane between the skin and the breast parenchyma to the level of the clavicle. The fascia of the pectoralis major muscle is then incised from the sternum to the edge of the lateral edge of the muscle with care to preserve the internal mammary perforators. The inferior flap is then developed to the level of the rectus muscle (just at or below the level of the inframammary fold). The underlying fascia is then incised from the sternum to the mid axillary line. The medial flap is then developed similarly, connecting the superior and inferior flaps, with attention to the internal mammary perforators in this area. As these vessels tend to retract, ligation of any bleeding vessel is performed. Unlike the other skin flaps, the lateral dissection tends to be less well defined. The flap is taken down to the level of the latissimus muscle. Care should be taken to avoid the axillary contents and sensory nerves. The breast is then removed en bloc with the fascia of the pectoralis muscle by retracting the breast downward and dissecting the plane between the muscle fibers and the fascia. The wound is then irrigated with warm sterile saline, and the flaps and chest wall are then systematically inspected to ensure hemostasis. A drain is then placed to prevent seroma formation. Skin closure can be performed in

different ways, such as with a 3-0 running polydioxanone suture with a 4-0 subcuticular stitch or with interrupted 3-0 Vicryl sutures with a 4-0 subcuticular stitch. Postmastectomy, the patient is admitted to the hospital overnight to ensure adequate pain control and to monitor for acute bleeding. When drain output is less than 30 mL for 2 consecutive days, the drain is removed (typically between postoperative days 7 and 14). No antibiotic coverage is necessary while drains are in place. In less than 1% of cases, hematomas can occur and if small can be observed. For large or enlarging hematomas (encompassing greater than one-fourth of the chest wall), surgical exploration is required to evacuate the hematoma and stop any sources of bleeding. Other complications associated with mastectomy include skin flap necrosis, pneumothorax, cellulitis, neurapraxia, and lymphedema.

Figure 74-24. Incision placement for modified radical mastectomy. The incision should include the nipple–areola complex, biopsy scar, and excess skin of the breast.

10 If immediate reconstruction is planned, a *skin-sparing* incision is made, which often consists of making a smaller horizontal ellipse around the nipple–areola complex, a circular incision just encompassing the nipple–areola complex, or a lollipop incision (Fig. 74-25). In some circumstances, the patient may be a candidate for a *nipple-sparing mastectomy* if her breasts are small to moderate in size, often no larger than a C cup, with minimal ptosis, and the breast cancer is an acceptable distance (often at least 2 cm) from the nipple. Tumor size, histology, or lymph node status is no longer considered exclusion criteria for nipple-sparing mastectomy, and current exclusion criteria include clinical involvement of the nipple areolar complex, PDB, bloody nipple discharge, multicentric disease,³⁰⁹ and/or inflammatory carcinoma.³¹⁰ Nipple-sparing mastectomies are often performed through an inframammary fold incision or a radial lateral incision. More recently, a lateral vertical incision has been described. This incision is associated with a significant reduction in hypertrophic scar formation versus the radial lateral incision.³¹¹ Intraoperatively, a biopsy of the retroareolar margin is performed and must be histologically negative for malignancy. BRCA mutation carriers are also candidates for nipple-sparing mastectomies. In a study of 26 patients with BRCA mutations undergoing prophylactic mastectomies, DCIS was identified in one patient compared with two cases of DCIS in the matched control group. There were no locoregional recurrences in the patients with BRCA mutations at 37 months of follow-up.³¹² These findings support that nipple-sparing options are reasonable for patients with BRCA mutations.

Figure 74-25. Skin-sparing mastectomy. **A:** The only skin removed was the nipple–areola complex. **B:** Cosmetic outcome after bilateral skin-sparing mastectomy and transverse rectus abdominis myocutaneous (TRAM) flap reconstruction.

Although the goal of a mastectomy is to completely remove the breast cancer and normal breast tissue, local recurrence remains a risk. The risk of local recurrence is 6% at 5 years in patients with no lymph node involvement and 16% at 5 years in patients with one to three lymph nodes involved. With the addition of radiation therapy, the risk of local recurrence decreases to 2%. When four or more lymph nodes are involved, the risk of recurrence is 26% at 5 years, decreasing to 6% with the addition of radiation therapy.³¹³

In women with a personal history of breast cancer, the absolute risk of contralateral breast cancer is estimated to be 0.5% to 1.0% per year or 5% to 10% during the 10 years following diagnosis.³¹⁴ As such, most women will not develop a contralateral breast cancer. As no randomized clinical trials have been performed, it is not known whether contralateral prophylactic mastectomy (CPM) is associated with a survival benefit in women with a personal history of breast cancer. However, a survival benefit for CPM has been shown for patients with a deleterious *BRCA1* or *BRCA2* mutation.^{315–318} The decision to perform a CPM must be individualized with each individual patient. Of note, a twofold increased risk of major complications exists with CPM when compared with unilateral mastectomy.^{319,320}

Breast Reconstruction

All patients undergoing mastectomy should be offered consultation with a plastic surgeon for consideration of breast reconstruction, recognizing that some women may choose to forego this procedure and prefer the use of a breast prosthesis. The two main types of breast reconstruction include implant-based and autologous tissue breast reconstruction. Implants include silicone or saline implants. Autologous tissue techniques used for breast reconstruction often include either the transverse rectus abdominis myocutaneous (TRAM) flap or the deep inferior epigastric perforator (DIEP) flap.

Breast reconstruction can be performed immediately after a mastectomy procedure (immediate reconstruction) or at a later time (delayed reconstruction). For implant-based breast reconstruction, the most common technique involves a two-stage method with placement of a tissue expander under the pectoralis major muscle at the time of the mastectomy (Fig. 74-26). The tissue expander can then be filled incrementally with saline with the first fill typically occurring 1 to 3 weeks postoperatively with additional fills every 1 to 2 weeks until the desired expansion is achieved. The tissue expander is then left in place for several months to allow for maximal skin remodeling. During the second stage, the tissue expander is removed and is replaced with a silicone or saline implant. This two-stage reconstruction method is particularly beneficial for women who will need adjuvant radiation therapy as radiation can result in flap necrosis, fibrosis, and shrinkage, resulting in poor cosmetic outcomes after immediate implant and/or tissue flap reconstruction. Instead, the tissue expander allows for skin preservation and the ability to then proceed with either an implant or autologous reconstruction at a later date. The complications associated with tissue expander placement include infection requiring removal. This occurs at a rate of 1.2% but may be higher in women being treated with chemotherapy

and/or radiation therapy.³²¹

Although silicone gel implants are superior to saline implants in terms of offering a more natural contour and texture, the use of silicone implants remains controversial secondary to unsubstantiated claims of a link between silicone implants and autoimmune disease first reported in 1992. Since that time, no studies have shown a causative relationship and the American College of Rheumatology and the FDA have concluded that there is no additional risk of connective tissue disease in patients with silicone implants.^{322–324}

A few case reports have noted an association between breast implants (saline or silicone) and anaplastic large cell lymphoma of the breast. There have been 60 cases of ALCL reported among an estimated 5 to 10 million women with breast implants. Although a causal relationship is not proven and the potential risk is extremely low, the FDA does require breast implant manufacturers to include this finding in the product labeling.³²⁵

Figure 74-26. Breast reconstruction with tissue expanders. Although the breasts are not identical, this is not evident when a bra is worn.

The primary benefit of autologous tissue breast reconstruction is that the reconstructed breast appears and feels more natural than following implant-based breast reconstruction. In addition, autologous tissue breast reconstruction may be the only option in patients who have undergone chest wall radiation, as skin fibrosis may preclude implant-based breast reconstruction. A common procedure is the free TRAM flap, which involves removing skin, subcutaneous fat, muscle, and associated blood supply from the lower abdomen. The blood supply includes the deep inferior epigastric artery and vein, which are anastomosed to the internal mammary or thoracodorsal arteries and veins. The TRAM flap is contoured to replicate the native breast. Similar to the TRAM flap, the DIEP flap uses the same lower abdominal skin and subcutaneous fat but spares the rectus abdominis muscle. In both methods, the donor site is closed as a modified abdominoplasty.

Radical Mastectomy

In 1907, Halsted presented to the American Surgical Association his results of 232 patients who underwent his radical mastectomy at Johns Hopkins. Halsted's radical mastectomy involved wide excision of skin via a teardrop incision extending across the deltopectoral groove, excision of the entire pectoralis major muscle, resection of the pectoralis minor muscle to expose the axillary contents for dissection, and excision of the supraclavicular lymph nodes. In certain cases, he also removed the mediastinal nodes. Immediate skin grafting was performed to close all of the wounds.³²⁶ With advances in breast cancer screening, adjuvant medical therapy, and radiation therapy, a concomitant evolution toward less radical surgery has ensued. A report by the American College of Surgeons Commission on Cancer demonstrated a dramatic decline in the use of the radical mastectomy from 47.9% of breast cancer cases in 1972 to 3.4% of cases in 1981.³²⁷ Furthermore, the **modified radical mastectomy**, which consists of a simple mastectomy and ALND, was considered a satisfactory alternative to the radical mastectomy by 1980.³²⁸ A randomized, prospective clinical study by W.A. Maddox in 1983 showed no significant differences in disease-free survival, overall survival, or local recurrence rates at 5 years for modified radical versus radical mastectomy. These differences are likely secondary to the routine use of chemotherapy for patients with involved axillary lymph nodes by this time period.³²⁹ When patients are not candidates for breast conservation and SLNB, a modified radical mastectomy is indicated. See the section on Axillary Lymph Node Dissection above.

Radiation Therapy

The primary indication for the use of radiation therapy in breast cancer is to reduce the risk of a locoregional recurrence following surgery and potentially improve survival by eradicating persistent locoregional disease that may be resistant to systemic therapy.

The standard approach for patients who undergo breast-conserving surgery is to deliver whole breast radiation therapy with a dose of 50 to 60 Gy. The regimen is often given in 2 Gy fractions 5 days a week for a total of 5 weeks. A 60 Gy regimen, which also includes a 10 Gy boost to the tumor bed, was found to be more effective for patients 45 years of age or younger, with a local relapse rate of 14% (60 Gy) compared to 28% (50 Gy) ($p < 0.0001$).³³⁰ Alternative radiation therapy strategies are currently under investigation including the use of rapid fractionation schedules, such as the delivery of 41 to 42 Gy over 15 fractions and accelerated partial breast radiation. Early results show excellent clinical outcomes.^{331–333}

Although most women do not require radiation therapy following mastectomy, postmastectomy radiation therapy is often recommended for women at high risk for locoregional recurrence, including women with four or more positive lymph nodes, tumor size greater than 5 cm, or with positive surgical margins. In these instances, postmastectomy radiation can reduce the rate of chest wall recurrence by 65% to 75%.^{70,334–337}

11 Of note, optimal locoregional management of the axilla remains to be defined. Both surgery and radiation therapy can be used to treat disease in the axilla. Previously, ALND was the preferred treatment modality for prevention or treatment of axillary disease. More recent studies suggest that radiation therapy may be equally effective with less morbidity. The EORTC AMAROS trial randomized patients with clinical T1-T2 N0 breast cancer to ALND or radiation therapy to the axilla after a positive SLNB.³³⁸ The two arms had comparable axillary control, but patients in the radiation therapy arm had significantly less morbidity. At 5 years, 23% of patients in the ALND arm had lymphedema compared to 11% in the radiation therapy arm. Currently, in patients with clinical T1-T2 N0 disease who undergo mastectomy with a positive SLNB, ALND is the standard approach as these patients were not included in the Z0011 study. However, findings from the AMAROS trial suggest that in this group of patients, radiation therapy may provide similar locoregional control with less morbidity.

Chemotherapy

The role of medical therapy is to eradicate breast cancer cells at the primary tumor site or at any other site in the body. Systemic therapies include but are not limited to chemotherapy, endocrine therapy, and targeted therapy.

The decision as to whether or not to treat patients with breast cancer with chemotherapy is complex. Considerations include patient age, menopausal status, AJCC TNM stage, histologic grade, biomarker profile, proliferation index, and medical comorbidities. Online calculators exist to estimate the risks and benefits of chemotherapy and other adjuvant therapies. Adjuvant! Online is a popular risk-benefit calculator that is based on population-wide data that focuses on recurrence risk and probability of survival. This is a Web-based program that is generated from collective data from the SEER database, the Early Breast Cancer Trialists Collaborative Group (EBCTCG), individual clinical trial results, and published literature.³³⁹ Other calculators include Cancermath.net³⁴⁰ and FinProg project.³⁴¹ Molecular profiling using Oncotype DX or similar molecular assay can be used for patients with node-negative ER+/HER2- breast cancers. For Oncotype DX, a score of ≥ 31 is associated increased risk of recurrence with a recommendation for administration of chemotherapy.

Adjuvant chemotherapy is often initiated 4 to 6 weeks after surgery. Although treatment earlier is not beneficial, a delay of greater than 12 weeks may be detrimental. If adjuvant radiation therapy is indicated, it is administered starting 3 to 4 weeks after completion of chemotherapy.

Anthracyclines (Doxorubicin, Daunorubicin, Epirubicin)

These compounds are derived from *Streptomyces* bacteria and function by inhibiting DNA and RNA synthesis by intercalating between base pairs of the DNA/RNA strand, blocking DNA transcription and replication by inhibiting topoisomerase II enzyme, generating free oxygen radicals, and by inducing histone eviction from chromatin. The main adverse effect is cardiotoxicity.

Taxanes (Paclitaxel, Docetaxel)

These compounds are derived from plants of the genus *Taxus* (yews) and function by disrupting microtubule formation and inhibiting mitosis. The main adverse effect is peripheral neuropathy. Given

that these compounds are not water soluble, allergic reactions to the diluent may result.

Cyclophosphamide

This compound is a nitrogen mustard alkylating agent that functions by adding an alkyl group to the guanine base of DNA, resulting in intrastrand and interstrand DNA cross-links and, therefore, interferes with DNA replication. The main adverse effects include acute myeloid leukemia, bladder cancer, hemorrhagic cystitis, and infertility.

5-Fluorouracil

This compound is an antimetabolite that works as an irreversible inhibitor of thymidylate synthase and, therefore, interferes with DNA synthesis. The main adverse effect is mucositis.

Methotrexate

This compound is both an antimetabolite and an antifolate that blocks dihydrofolate reductase and, therefore, inhibits the synthesis of folic acid, which is essential for DNA, RNA, thymidylate, and protein synthesis. The main adverse effect is ulcerative stomatitis.

Platinum Agents (Carboplatin or Cisplatin)

These compounds bind to and cause cross-links in DNA, triggering apoptosis. The main adverse effects are nephrotoxicity, neurotoxicity, and ototoxicity.

Endocrine Therapy

Patients with all stages of breast cancer that express the ER or PR are candidates for endocrine therapy. In the premenopausal setting, the focus is on blocking ovarian function and the effects of estrogen. In postmenopausal women, the ovaries are no longer the predominant source of estrogen, but instead estrogen is synthesized mainly from nonglandular sources such as subcutaneous fat. As such, blocking estrogen production is very effective in the postmenopausal population.

Blocking Ovarian Function (Leuprolide, Goserelin, Buserelin)

As the ovaries are the main source of estrogens in premenopausal women, ovarian ablation can be achieved either surgically by removal of the ovaries or through medical therapy with luteinizing hormone-releasing hormone agonists such as goserelin or leuprolide. These compounds function by binding to the gonadotropin-releasing hormone receptor, resulting in initial FSH and LH release. However, with prolonged drug exposure, desensitization of the pituitary occurs whereby the levels of LH and FSH become profoundly suppressed. This results in inhibition of the growth of ovarian follicles and steroidogenesis.

Blocking Estrogen at the Receptor (Tamoxifen, Raloxifene, Fulvestrant)

As SERMs, tamoxifen and raloxifene competitively bind to the ER and prevent estrogen from binding. As a selective estrogen receptor down-regulator (SERD), fulvestrant binds to the ER and targets it for destruction. Fulvestrant is used in postmenopausal women who have hormone receptor-positive metastatic disease who experience progression following endocrine therapy.

Blocking Estrogen Production (Anastrozole, Letrozole, Exemestane)

The enzyme aromatase converts androgenic substrates to estrogen, and, therefore, its inhibition can effectively decrease plasma levels of estrogen. Nonsteroidal AIs include anastrozole and letrozole, whose binding activity can be reversed. Exemestane is a steroidal AI that irreversibly binds aromatase and permanently inactivates it.

Targeted Therapy

Targeted Therapy for HER2+ Breast Cancers

Amplification or overexpression of the human epidermal growth factor receptor 2 (HER2) is present in approximately 20% of primary breast cancers. Given that effective targeted therapies exist for these patients, all newly diagnosed breast cancers are routinely tested for HER2 expression/amplification.

Trastuzumab is a monoclonal antibody that targets HER2+ breast cancers by multiple mechanisms including (1) interfering with the homo- and heterodimerization of HER2 and inhibiting mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K/Akt) signaling pathways, (2) immune-mediated killing of tumors that overexpress HER2 by a mechanism referred to as antibody-

dependent cellular cytotoxicity (ADCC), and (3) triggering HER2 internalization and degradation through promoting the activity of tyrosine kinase-ubiquitin ligase c-Cbl.

Pertuzumab is a monoclonal antibody that interferes with the dimerization of HER2 to HER3, therefore, interfering with MAPK and PI3K pathway activation. It also induces antibody-dependent cell-mediated cytotoxicity (ADCC).

Trastuzumab emtansine (T-DM1) is an antibody–drug conjugate that consists of trastuzumab linked with the cytotoxic agent mertansine (DM1). While trastuzumab binds to the HER2 receptor, mertansine enters the cell and destroys it by binding to tubulin. This allows toxin to be targeted specifically to the cancer cell.

Targeted Therapy for Triple Negative Breast Cancers (Experimental Options)

Although patients with TNBC often have an excellent response to chemotherapy, overall outcomes are worse compared to patients with ER⁺ and/or HER2⁺ disease.^{236,342,343} The lack of effective targeted therapies for TNBCs likely contributes to this disparity in outcome. Drugs-targeting TNBCs are in clinical trials and include inhibitors targeted to the epidermal growth factor receptor (cetuximab), angiogenesis (bevacizumab), DNA damage or poly adenosine diphosphate-ribose polymerase (olaparib, veliparib, iniparib), the proto-oncogene Src (dasatinib), and histone deacetylase (vorinostat). Given the heterogeneity of TNBC, multitargeted therapy will likely be needed to eradicate this disease.

Treatment Regimens

Adjuvant Medical Therapy for Hormone Receptor-Positive or Negative, HER2-Negative Breast Cancer

For patients at high risk for recurrence, a regimen based on the combination of an anthracycline and taxane has been proven to be the most effective. This combination is commonly given in a dose-dense fashion (whereas traditional chemotherapy is given every 3 weeks, this requires administration every 2 weeks) with doxorubicin (60 mg/m²) and cyclophosphamide (600 mg/m²) for four cycles, followed by paclitaxel (175 mg/m²) every 2 weeks for four cycles. The data to support this regimen come from an EBCTCG meta-analysis. In this study published in 2011, anthracycline-based regimens were compared to CMF (cyclophosphamide, methotrexate, and 5-Fluorouracil), and to no treatment. Both chemotherapy regimens resulted in a significant decrease in the risk of recurrence and a reduction in both breast cancer and overall mortality versus no treatment at 10 years. There was no difference between the anthracycline and CMF treatment regimens with standard doses of doxorubicin (four cycles with 60 mg/m² with a cumulative dose of 240 mg/m²). However, at higher doses of anthracyclines (>240 mg/m²), there was a reduction in the risk of recurrence (absolute difference of 2.6%), a reduction in breast cancer mortality (absolute difference of 4.1%), and a reduction in overall mortality (absolute difference of 3.9%) at 10 years. By 2012, taxanes were routinely combined with anthracycline-based therapies (ACTHs) and the combination regimen resulted in a reduction in the risk of recurrence (absolute difference of 4.6%), a reduction in breast cancer mortality (absolute difference of 2.8%), and a reduction in overall mortality (absolute difference of 3.2%). In addition, the benefits of taxanes were independent of age, nodal status, tumor size, tumor grade, and ER status.^{344,345}

Although AC-T has been shown to result in the greatest improvement in outcome, there is no single chemotherapy regimen that is the standard of care as preferred combinations vary by institution, geographic region, and by medical oncologist. Other anthracycline-based regimens include FEC (fluorouracil 500 mg/m², epirubicin 100 mg/m², and cyclophosphamide 500 mg/m²) given every 3 weeks for six cycles and FEC-Taxane (FEC every 3 weeks for three cycles, followed by docetaxel 100 mg/m²) for three cycles or FEC for four cycles, followed by weekly paclitaxel (100 mg/m²) for 8 weeks. For patients who are not candidates for anthracycline-based regimens, TC can be administered (docetaxel 75 mg/m² plus cyclophosphamide 600 mg/m²) for four cycles given every 3 weeks. CMF (cyclophosphamide 100 mg/m² orally days 1 to 14, methotrexate 40 mg/m² IV days 1 and 8, and 5-fluorouracil 600 mg/m² IV days 1 and 8) for six cycles every 4 weeks is another alternative regimen.

After chemotherapy, for patients with ER⁺ breast cancer, endocrine therapy should be initiated, as multiple meta-analyses have consistently shown improved survival outcomes with its use. The choice of endocrine therapy is dependent on menopausal status, with menopause being defined as the lack of menstruation for at least 12 months in the absence of tamoxifen, chemotherapy, or ovarian suppression. Menopause can also be achieved surgically with the removal of both ovaries.⁷⁰ In premenopausal women, the preferred agent is tamoxifen, which is a SERM that inhibits the growth of breast cancer cells. In the 2011 EBCTCG meta-analysis, women who took tamoxifen for 5 years had a significant

reduction in the risk of breast cancer recurrence (40%) and breast cancer mortality (30%) at 15 years.³⁴⁶ For premenopausal women who cannot tolerate tamoxifen secondary to side effects, ovarian suppression should be considered and can be accomplished through surgical resection of both ovaries or by administration of a luteinizing hormone-releasing hormone agonist such as leuprolide or goserelin. Although not as effective as tamoxifen therapy, ovarian suppression results in a significant reduction in the risk of recurrence (25%) and a significant reduction in breast cancer mortality (29%) compared with observation.²⁶⁵

In postmenopausal women, AIs have consistently been shown to be superior to tamoxifen, as supported by an intention to treat meta-analysis that included 37,000 postmenopausal women with ER⁺ breast cancer. The AI treatment group had a significant reduction in breast cancer recurrence and breast cancer mortality.³⁴⁷ Furthermore, in the NCIC CTG MA.17 trial that included more than 5,000 postmenopausal women, who had completed a 5-year course of tamoxifen, followed by an additional course of letrozole or placebo – the letrozole treatment group at follow-up of 64 months had improvement in disease-free survival and overall survival.^{348–350} The different AIs have been shown to have similar efficacies and as such there is not one that is preferred. Postmenopausal women, who cannot tolerate an AI because of osteoporosis, AI-associated musculoskeletal syndrome, or cardiac disease, can be treated with tamoxifen. Premenopausal women should not be treated with an AI as it can result in reactivation of ovarian function.^{351,352}

The optimal duration of endocrine therapy has also recently been studied. In the Adjuvant Tamoxifen: Longer Against Shorter (ATLAS) trial, 15,000 women were assigned to treatment with tamoxifen for 5 years or 10 years. It was found that the group receiving tamoxifen for 10 years had a reduction in the risk of recurrence, significant reduction in breast cancer mortality after year 10, and a significant reduction in the incidence of contralateral breast cancer. However, this was also associated with an increased cumulative incidence of endometrial cancer (3.1% vs. 1.6%), pulmonary embolus (1.2% vs. 0.6%), and ischemic heart disease (4% vs. 2%).³⁵³ Further supporting the use of tamoxifen for 10 years is the Adjuvant Tamoxifen-To Offer More trial that enrolled 7,000 women. The 10-year tamoxifen treatment group had a significant reduction in the risk of recurrence and a trend toward a reduction in mortality. However, there was an increased cumulative incidence of endometrial cancer and deaths from endometrial cancer. As such, women with more aggressive ER⁺ breast cancers (high grade, tumor size >2 cm, pathologically involved lymph nodes) should be offered tamoxifen for 10 years, understanding the associated risks.³⁵⁴ Similarly, in the MA.17R trial extending the use of AIs to 10 years has been shown to decrease the rate of breast cancer recurrence and the development of primary breast cancer in the contralateral breast.³⁵⁵

For patients with ER-/PR-/HER2- or TNBC, chemotherapy is critical as no targeted therapies exist for these patients. Adjuvant chemotherapy has been shown to provide a larger benefit for patients with TNBC than for those with hormone-positive disease, with a larger reduction in the risk of recurrence and subsequently a higher absolute improvement in disease-free survival (23% vs. 7%). Furthermore, there was a larger reduction in the risk of death and as such a higher absolute improvement in overall survival (17% vs. 4%).³⁵⁶ There is no standard chemotherapeutic regimen for patients with TNBC; however, anthracycline- and taxane-based therapies remain the most commonly used. Taxanes are known to be associated with a significant improvement in disease-free survival for patient with TNBCs at 7 years, as seen in the GEICAM 9906 trial comparing FEC versus FEC, followed by paclitaxel.³⁵⁷ In addition, the use of platinum agents has been introduced for patients with TNBC. As most breast cancers that arise in the setting of a germline mutation in *BRCA1* are triple negative and the role of *BRCA1* relates to DNA damage response and cell cycle checkpoint control, it has been hypothesized that platinum agents (as DNA-damaging agents) would have a role in *BRCA1*-induced breast cancers. In one clinical trial involving 107 women with stage I to III breast cancers treated with cisplatin for four cycles prior to neoadjuvant chemotherapy, the pathologic complete response was 61%.³⁵⁸ Given that it is known that pathologic complete response in patients with TNBCs is associated with an improvement in disease-free survival, platinum-based therapy is very promising.^{359,360} However, it is not currently known how platinum agents impact survival.

Patients with TNBC have a poorer prognosis compared with patients with other breast cancer subtypes. These patients have a worse breast cancer-specific survival, worse overall survival, and a dramatic increase in death within 2 years of diagnosis. However, this risk declines substantially over time.³⁶¹ Given these risks, chemotherapy is now commonly given in the neoadjuvant setting, especially for patients with locally advanced TNBCs.

Adjuvant Medical Therapy for HER2-Positive Breast Cancer

Approximately 20% of women diagnosed with primary invasive breast cancer will have either an amplification or overexpression of the HER2. Since the introduction of trastuzumab to adjuvant chemotherapy, women with early and locally advanced HER2 positive disease have had tremendous improvements in both disease-free survival (HR for recurrence, 0.60; 95% CI, 0.50 to 0.71) and overall survival (HR for mortality, 0.68; 95% CI, 0.57 to 0.77), as evidenced in a meta-analysis of eight trials involving approximately 12,000 women that compared trastuzumab plus chemotherapy versus chemotherapy alone. The risks associated with trastuzumab therapy include congestive heart failure and a decline in left ventricular ejection fraction.³⁶² Trastuzumab is the only HER2-targeted therapy to result in a survival benefit when administered with chemotherapy in the adjuvant setting. Based on collective data from the Herceptin Adjuvant (HERA) trial³⁶³ and the Protocol for Herceptin as Adjuvant therapy with Reduced Exposure (PHARE) trial,³⁶⁴ the duration of adjuvant trastuzumab treatment should be 1 year.

It is recommended that women with HER2 positive, node-positive breast cancer and women with HER2-positive, node-negative tumors >1 cm in size receive both adjuvant chemotherapy and trastuzumab. Chemotherapy regimens include both anthracycline-based (ACTH: doxorubicin 60 mg/m² and cyclophosphamide 600 mg/m² every 3 weeks for four cycles, followed by docetaxel 100 mg/m² every 3 weeks and trastuzumab [weekly during chemotherapy and then every 3 weeks for 1 year]) and non-anthracycline-based therapies (TCH: docetaxel 75 mg/m² plus carboplatin every 3 weeks for 6 cycles, with trastuzumab [weekly during chemotherapy and then every 3 weeks for 1 year]). The effectiveness of anthracycline-based chemotherapy has been validated with the National Surgical and Breast and Bowel Project (NSABP B-31) trial and the North Central Cancer Treatment Group (NCCTG) N-9831 trial. With a median follow-up of approximately 4 years, chemotherapy plus adjuvant trastuzumab resulted in superior rates of disease-free survival and overall survival.³⁶⁵ Non-anthracycline-based therapy (TCH) has been contrasted with ACTH in the Breast Cancer International Research Group 006 (BCIRG-006) trial, and it was determined that ACTH demonstrated a trend toward improved disease-free and overall survival that did not reach statistical significance. However, ACTH had greater toxicity than TCH.³⁶⁶ As such, both ACTH and TCH are reasonable options for women with HER2-positive breast cancer.

Although trastuzumab has significantly improved survival outcomes for patient with HER2+ breast cancer and has paved the way for the era of targeted therapy in breast cancer treatment, inherent or acquired mechanisms of resistance to trastuzumab therapy can occur, resulting in the need for more effective anti-HER2 therapies.³⁶⁷ A once promising HER2- directed therapy that has recently been shown to have no effect in the adjuvant setting is lapatinib, a tyrosine kinase inhibitor that has dual effects against both HER2 and the epidermal growth factor receptor. In a placebo-controlled, multicenter, randomized phase III trial, women with HER2-positive early- breast cancer who had previously received adjuvant chemotherapy but not trastuzumab were randomly assigned to receive daily lapatinib or placebo for 12 months. At a median follow-up of 48 months, there were no differences in mortality or in local/distant recurrences.³⁶⁸ Furthermore, as presented in the 2014 ASCO meeting, the Adjuvant Lapatinib And/Or Trastuzumab Treatment Optimisation Study (ALTTO) showed a lack of benefit for combining lapatinib with trastuzumab as there was no impact on disease-free survival compared with adjuvant trastuzumab alone.³⁶⁹ Novel HER2-targeted therapies include pertuzumab, which has been approved for HER2-positive breast cancer in both the neoadjuvant and metastatic settings in conjunction with chemotherapy and trastuzumab.⁷⁰ Overall survival benefits are not known at this time and the benefits of adjuvant pertuzumab is being explored in randomized trials. Another promising HER2-targeted therapy under clinical investigation is TDM1, which consists of trastuzumab linked with the cytotoxin mertansine, which should result in more specific and robust targeting of HER2-positive breast cancer cells.³⁷⁰

SPECIAL ISSUES IN BREAST CANCER TREATMENT

Inflammatory Breast Cancer

A common clinical presentation for IBC is *peau d'orange*, characterized by edema, warmth, and erythema. Unlike other types of breast cancer, patients with IBC often have associated pain and tenderness with an enlarged and firm breast. The nipple can also be involved with flattening, erythema, crusting, blistering, and retraction. Despite the reference to inflammation, the skin changes are not secondary to an inflammatory process but rather secondary to tumor emboli within the dermal

lymphatics.³⁷¹ As noted by Sir Charles Bell in 1812, these cancers tend to be much more aggressive —“when a purple color is on the skin over the tumor accompanied by shooting pains, it is a very unpropitious beginning.”³⁷² By 1924, Lee and Tannenbaum³⁷³ described 28 cases of women presenting with a rare, rapidly progressive breast cancer with inflammatory features and introduced the term “inflammatory breast cancer.

IBC is an aggressive form of LABC that effects approximately 1% to 5% of women with breast cancer.³⁷⁴ It is designated as primary tumor stage T4d. The consensus-based criteria for the diagnosis of IBC was determined by an international expert panel who proposed the following features: (1) rapid onset of breast erythema, edema, and/or *peau d’orange*, and/or warm breast, with or without an underlying palpable mass, (2) duration of history no more than 6 months, (3) erythema occupying at least one-third of the breast, and (4) pathologic confirmation of invasive carcinoma.³⁷⁵ Furthermore, although dermal lymphatic involvement supports the diagnosis of IBC, which can be obtained with a full-thickness skin punch biopsy, it is neither necessary nor sufficient in the absence of the classical clinical findings. The diagnosis of IBC is made with clinical examination findings, followed by breast imaging, which includes mammography and ultrasound to help detect sites within the breast that can be biopsied to confirm the breast cancer. To determine extent of disease, we routinely obtain a breast MRI. A skin punch biopsy can then be performed but is not required for diagnosis. As IBC is a clinically and pathologically distinct form of LABC that is particularly fast growing, invasive, and angiogenic, nearly all women have lymph node involvement at the time of presentation and approximately a third of patients will have distant metastases.^{376,377} As such, all women with IBC need to undergo complete staging including a chest/abdomen/pelvic CT scan and bone scan. Head CT should be considered if symptoms are present.

The treatment of IBC is based on multimodality treatments, similar to those described for women with LABC. However, BCT, SLN biopsy, and immediate breast reconstruction are generally considered inappropriate for patients with IBC. Treatment often consists of neoadjuvant chemotherapy that is anthracycline- and taxane-based until all signs of skin inflammation have resolved and the breast and axillary masses are deemed operable. Surgical management with a modified radical mastectomy is then performed with delayed breast reconstruction, if appropriate. Adjuvant radiation therapy follows using standard fields determined by CT planning, ensuring that the chest wall, supraclavicular, infraclavicular, and the internal mammary lymph nodes are radiated.³⁷⁵ Radiation therapy to the axillary bed after axillary dissection is often individualized. However, if the patient still remains inoperable after neoadjuvant chemotherapy, then radiation therapy ensues, with the goal that the patient will thereafter become operable. For ER⁺ IBC, adjuvant endocrine therapy is given. For HER2⁺ IBC, trastuzumab (+/- pertuzumab) is added to the neoadjuvant regimen and adjuvant trastuzumab is given to complete 1 year of treatment.

Currently, there is no optimal systemic regimen (chemotherapy or targeted therapy) identified for IBC. However, patients who obtain a complete pathologic response from chemotherapy have a significantly higher disease-free survival and overall survival.^{378,379} Despite the combination of surgery and radiation therapy improving locoregional control, there is no impact on overall survival.³⁸⁰ Even with multimodality treatments, the prognosis for patients with IBC remains poor with 5-year disease-free survival rates of 20% to 45% and an overall survival of 30% to 70%.^{378,380–383}

Breast Cancer in the Elderly

In the United States, approximately half of newly diagnosed breast cancers are in older women, typically defined as aged 65 years or older. Older patients tend to receive less than standard therapy worldwide,^{384–387} with decreased rates of surgery and use of adjuvant radiation therapy, but with increased use of primary endocrine therapy.³⁸⁸ This may be secondary to more indolent tumors present in elderly women versus younger women.³⁷⁹ However, after controlling for confounding factors such as comorbidity, social support, and functional status, older women are still treated less aggressively than their younger counterparts. In general, treatment approaches should not be altered for medically fit older women, except for the use of SLNB and/or radiation therapy in early ER⁺ disease.

The ability to omit axillary surgery without an adverse effect on outcome in older women (age ≥70 years) with favorable breast cancers has been well studied and supported by multiple randomized trials. These women had clinically negative axillary examinations, small (<2 cm) ER⁺ breast cancers, and were all treated with adjuvant endocrine therapy.^{390–392}

The ability to omit adjuvant radiation therapy in older women who have undergone partial mastectomy for early ER⁺ breast cancer is supported by CALGB 9343. This phase III study involved 636

women (age ≥ 70 years) who had T1N0M0 ER+ breast cancer who were treated with partial mastectomy and then randomly assigned to receive either radiation therapy plus tamoxifen (317 women) or tamoxifen alone (319 women). The primary end points studied included time to local or regional recurrence, frequency of mastectomy, breast cancer-specific survival, time to distant metastasis, and overall survival. At 10 years, 98% of patients receiving radiation therapy plus tamoxifen compared with 90% of those receiving tamoxifen alone were free from local and regional recurrences. However, there were no significant differences in time to mastectomy, time to distant metastasis, breast cancer-specific survival, or overall survival between the two groups. Ten-year overall survival was 67% (95% CI, 62% to 72%) and 66% (95% CI, 61% to 71%), respectively.³⁹³ This led to breast-conserving surgery and endocrine therapy alone being incorporated as a category I recommendation in the current NCCN Guidelines for older women.

For older women with comorbidities, functional status limitation, or frailty, the Comprehensive Geriatric Assessment (CGA) can serve as an objective measure to aid in treatment decisions. The CGA has been used in elderly patients with cancer including those with breast cancer and ranges from 44 to 84 questions. The ELCAPA study looked at how the CGA could alter an initial treatment plan in 375 patients aged 70 years and older. Treatment plans were modified in 20.8% of cases, with most plans changed to decrease treatment intensity, although there were some regimens (10.8%) that were intensified.³⁹⁴ Given how extensive the full CGA can be, other screening tools that have been developed include the Vulnerable Elders Survey-13, Barber Questionnaire, Geriatric 8, Cardiovascular Health Study, and the abbreviated CGA.

For medically frail patients, surgical management, followed by observation is commonly offered, especially if a patient's life expectancy is limited. If surgical intervention is not an option, endocrine therapy can be offered to patients with ER+ disease and single agent chemotherapy for those with ER- disease. In the presence of HER2+ disease, single agent HER2-directed therapy or its addition to systemic therapy can be prescribed, understanding that the latter approach carries additive risks of toxicity. Radiation therapy is not recommended unless local control of disease is needed for symptom management. Finally, palliative and supportive care services need to be offered to patients who wish to avoid both surgical and systemic therapies.

Breast Cancer during Pregnancy

Gestational breast cancer is a rare disease affecting approximately 1 in 1,000 pregnancies but may become more common as women delay childbearing.³⁹⁵⁻³⁹⁸ It is defined as breast cancer that is diagnosed during pregnancy, within the first postpartum year, or anytime during lactation. Similar to nonpregnant women, women with gestational breast cancer present most often with a breast mass or skin thickening. Any mass that persists for greater than 2 weeks needs diagnostic imaging and possible biopsy.

The breast becomes engorged and hypertrophied during pregnancy making imaging more difficult. When women present with a mass in pregnancy, ultrasound is first obtained, which can differentiate between a simple cyst, a complex cyst, or a solid tumor. The majority of gestational breast cancers present as a focal solid mass.^{399,400} In the presence of an abnormal ultrasound, a diagnostic mammogram can then be obtained to further determine the extent of disease and has been shown to be safe in pregnancy as long as abdominal shielding is used.⁴⁰¹ Although MRI with gadolinium has been shown to be more sensitive than mammography for detecting invasive breast cancer, gadolinium is contraindicated in pregnancy. MRI has also not been systemically studied for the evaluation of breast masses in pregnancy or lactation. All suspicious masses must be biopsied, even in the presence of normal imaging studies, through core needle biopsy, incisional biopsy, or excisional biopsy. In a patient who has a concerning axillary examination, FNA biopsy is indicated.

The most common histologic type of gestational breast cancer is IDCs that are poorly differentiated and diagnosed at an advanced stage. Compared to nonpregnant women, women with gestational breast cancers have less hormone receptor-positive breast cancers (approximately 25% vs. 55% to 60%).^{402,403} The association between HER2 disease and gestational breast cancer is not currently known. For pregnant or lactating women with locally advanced disease, staging evaluation is necessary. Given the large cumulative radiation dose that can be associated with computed tomographic scans and the contraindication for gadolinium use (therefore limiting the utility of MRI) in pregnancy, staging imaging for pregnant women commonly includes chest radiography, an abdominal ultrasound of the liver, and a "low-dose" bone scan or a skeletal MRI.

For women diagnosed with breast cancer at an early gestational age, pregnancy termination is an

option. However, studies have not shown better outcomes with early termination. In a study involving 176 patients, pregnancy did not directly affect the prognosis of breast cancer, instead poor survival was related to younger age (younger than 40 years) and to the large number of ER-negative tumors (71%).⁴⁰⁴ Multiple subsequent studies have shown that pregnancy does not have a negative impact on overall survival.^{405–407} In 2012, a meta-analysis involving 3,000 patients with gestational breast cancer who were compared to 37,100 controls found that gestational breast cancer was associated with a higher risk of death. However, this was limited to women diagnosed in the postpartum period.⁴⁰⁸

The treatment for breast cancer for women diagnosed in the postpartum or lactational period does not differ from that recommended for nonpregnant patients. However, for patients receiving chemotherapy, trastuzumab, or endocrine therapy, breast-feeding is not recommended given the potential toxicity to the infant. The treatment for pregnant women does not differ significantly from established guidelines but includes modifications to ensure the safety of the developing fetus. During any trimester of pregnancy, surgical and anesthetic risks to the fetus have been shown to be minimal.^{409–412} Mastectomy can be performed and for early breast cancers, this can eliminate the need for radiation therapy as it is contraindicated in pregnancy. Typical radiation doses used for breast cancer range from 46 to 60 Gy, which has been shown to convey a first trimester fetal dose of 0.04 to 0.15 Gy or a third trimester dose as high as 2 Gy.^{406,413} The threshold determined for prenatal radiation exposure for fetuses under 16 weeks of gestation is 0.10 to 0.20 Gy and after 16 weeks 0.50 to 0.70 Gy to avoid risk of congenital malformations.⁴¹⁴ As such, breast-conserving treatment (which necessitates radiation therapy) remote from delivery is not a feasible option. Otherwise, the choice between breast-conserving surgery and mastectomy can be guided by a patient's preference and the biology of the tumor.

Although the efficacy and safety of SLN biopsy has not been well established in pregnant women with invasive breast cancers, most institutions do perform SLN biopsy for axillary staging. Isosulfan blue dye is contraindicated in pregnant women, and methylene blue when used in amniocentesis has been associated with fetal complications. However, a small series of studies using methylene blue or double-filtered technetium sulfur for SLNB have suggested its safety and success in pregnant women.^{415–418} Given the small number of pregnant patients included in these studies, the potential risks of methylene blue and technetium sulfur to the fetus along with the potential inaccuracy of SLNB in pregnancy need to be discussed with the patient preoperatively. At our institution, single agent technetium sulfur is used for SLN mapping in pregnant patients.

The most common regimens used in gestational breast cancers are anthracycline-based, AC (doxorubicin plus cyclophosphamide), or FAC (fluorouracil plus AC). The exposure of the fetus during organogenesis or the first trimester to chemotherapy can be detrimental and conveys risks including congenital abnormalities, chromosomal abnormalities, and miscarriage. Although chemotherapy exposure in the second and third trimesters is not associated with organogenesis, risks of intrauterine growth restriction, lower gestational age at birth, and low birth weight occur in about half of exposed infants.^{419–422} As such, chemotherapy is often initiated after the first trimester and given its association with transient neonatal myelosuppression, it should be avoided 3 to 4 weeks prior to delivery. When possible, timing of delivery is restricted to 34 or more weeks of gestation and requires confirmation of fetal lung maturity to minimize complications associated with prematurity. Given that gestational breast cancer can present as locally advanced disease, neoadjuvant chemotherapy can be first given, followed by surgery in the postpartum period, and if indicated, adjuvant radiation therapy and endocrine therapy can then be initiated. For women who are diagnosed late in pregnancy or the postpartum/lactational period, prior to commencement of chemotherapy, which may impair fertility, these women should be offered consultation with a reproductive endocrinologist to discuss fertility-preserving options.

Trastuzumab is contraindicated in pregnancy given its association with oligohydramnios, which can result in fetal death, pulmonary hypoplasia, and fetal developmental abnormalities.^{423,424} The use of methotrexate and endocrine therapy is also contraindicated during pregnancy. These therapies can be initiated in the postpartum period.

Given that the majority of women diagnosed with gestational breast cancers are of reproductive age, many desire additional pregnancies. In a meta-analysis of 14 studies, 1,244 women who became pregnant following breast cancer were compared to 18,145 control patients. Pregnancy in breast cancer survivors did not convey a worse survival but suggested a protective effect. Some suggest that pregnancy may have an unknown biologic antitumor effect, although more likely this is secondary to healthier women with better prognosis choosing to reproduce over their sicker peers and, therefore, resulting in a bias toward improved survival. As most recurrences happen within the first 2 years after diagnosis and treatment, it is generally recommended that pregnant women wait 2 years before

contemplating another pregnancy.

Breast Cancer in Men

Male breast cancer in the United States accounts for 0.5% to 1% of all breast cancers diagnosed annually.⁴²⁵ Risk factors for male breast cancer include family history of breast cancer and genetic mutations including *BRCA1* and *BRCA2*. *BRCA2* is more commonly associated with male breast cancer and conveys a 6% lifetime absolute risk, which is an approximately 100-fold higher risk than that in the general male population.⁴²⁶ As such, all men diagnosed with breast cancer need genetic counseling and BRCA testing. Other genetic mutations include *PTEN*, which is linked to Cowden syndrome, *TP53*, which is associated with Li–Fraumeni syndrome, mismatch repair genes that are linked to hereditary nonpolyposis colorectal cancer (Lynch syndrome), and *PALB2* mutations.^{427,428} Other risk factors include those that increase circulating estrogens such as hormonal therapies, hepatic dysfunction, obesity, marijuana use, and thyroid disease. It is also associated with Klinefelter syndrome, which is characterized by 47XXY genotype. These male patients have atrophic testes and gynecomastia. In addition, they have high-serum concentrations of gonadotropins (follicular-stimulating hormone, luteinizing hormone) and a low-serum testosterone level, resulting in a high ratio of estrogen to testosterone. Those with Klinefelter syndrome have a 19.2- and 57.8-fold increase in the incidence of and mortality from breast cancer.⁴²⁹ Primary testicular conditions (orchitis, undescended testes, testicular injury) are associated with an increased risk of male breast cancer as it can result in lower androgen production and, therefore, result in a higher than normal estrogen to androgen ratio.^{430,431}

Unfortunately, men are often diagnosed with breast cancer at an advanced stage. They commonly present with a firm retroareolar mass that is painless. Workup for a suspicious breast mass in men is similar to that for women and includes a mammogram and biopsy. Ultrasound is typically less informative. The most common histologic subtype is invasive ductal carcinoma (90%). Lobular carcinoma is rarely diagnosed in men. DCIS is also less frequent in men versus women. Most male breast cancers are ER⁺ (81.5%).⁴³² The staging system for male breast cancers is similar to that for women and is classified according to the TNM AJCC staging system.

The treatment of early stage male breast cancer has generally been a modified radical mastectomy. However, for a man with a clinically negative axillary examination, an expert panel from the American Society of Clinical Oncology considers SLN biopsy to be an “acceptable” method.²⁴⁸ It is generally accepted that in men who have no evidence of disease in the SLN biopsy, no further axillary surgery is needed. For men who have a positive SLN, given there is a lack of data for men, they should be treated similarly to women with positive SLN biopsies. There are limited data regarding the use of breast-conserving surgery in men. A retrospective study of seven men treated with breast-conserving therapy followed for a median of 67 months reported that there was no recurrence of disease. If men do elect for a partial mastectomy, adjuvant radiation therapy is essential and is based on results showing that adjuvant radiation therapy after breast-conserving surgery for women conveys a survival advantage.⁴³³ For men with LABC (T3N0, N1-2, or T2N2) or IBC, treatment plans are similar to that for women. Consideration for neoadjuvant chemotherapy prior to surgery should be made. The treatment of metastatic breast cancer in males should parallel that for females.

Adjuvant chemotherapy, radiation therapy, anti-HER2 therapy, and endocrine therapy should mirror those for women. As the majority of male breast cancers are ER-positive, endocrine therapy with tamoxifen should be given. In a limited study involving 39 men, those treated with tamoxifen had better 5-year actuarial survival (61% vs. 44%) and disease-free survival (56% vs. 28%).⁴³⁴ Although there are limited data, tamoxifen appears to be superior to AIs in the adjuvant setting for male breast cancer.⁴³⁵ Extrapolating from the ATLAS trial for women,³⁵³ for men with higher risk of breast cancers, consideration toward extending tamoxifen to 10 years should be considered.

Male patients with breast cancer should undergo similar posttreatment surveillance as that recommended for females. However, the role of screening mammography for the contralateral breast in these men has not been explored. It is important to recognize that male patients with breast cancer are at risk for developing secondary cancers such as those of the small intestine, rectum, skin (nonmelanoma), pancreas, and prostate.⁴³⁶

Locoregional Breast Cancer Recurrence

Breast cancer recurrence can occur after both mastectomy and BCT (partial mastectomy and radiation therapy), with the median time to recurrence after mastectomy of 2 to 3 years versus 3 to 4 years after BCT.^{437–439} When breast cancer reappears on the chest wall, it is defined as a local recurrence. However, breast cancer that involves the lymph nodes such as the ipsilateral axillary, supraclavicular, infraclavicular, or internal mammary nodes is referred to as a regional recurrence. Among patients who undergo mastectomy for an operable breast cancer, 5% to 10% of patients will have a local or regional recurrence within 10 years whereas patients who undergo BCT have a risk of 10% to 15%, and in patients who forego radiation therapy after a partial mastectomy, the risk of recurrence is as high as 35%.⁴⁴⁰ Although BCT is associated with an increased risk of locoregional recurrence, there are no differences in overall survival as supported by a single institutional National Institutes of Health randomized study ($n = 237$)²⁷⁸ and two European randomized trials (EORTC trial 10801 and DBCG trial 82-TM). The latter involved approximately 1,800 patients with stage I and II breast cancer who were randomized to undergo a modified radical mastectomy or BCT. Patients who developed a local recurrence in these trials were then analyzed for survival and time to subsequent local recurrence after salvage treatment. There were no differences between the two groups in regard to survival and time to subsequent local recurrence after treatment of an early locoregional recurrence.⁴³⁷

The primary risk factors for postmastectomy recurrence include the size of the primary cancer and the number of positive axillary lymph nodes, where ≥ 4 involved nodes have been consistently shown to increase axillary recurrence rate to more than 20%.⁴⁴¹ In women with four or more positive lymph nodes, tumor size larger than 5 cm, or those with positive surgical margins, postmastectomy radiation therapy is often recommended as it can reduce the rate of chest wall recurrence by 65% to 75%.^{70,334–336} The most common presenting sign of a postmastectomy recurrence is a clinical mass or multiple small nodules on the chest wall or overlying skin in or near the mastectomy scar/skin flaps. Other signs of a recurrence can include inflammatory changes without an associated mass and painless masses found in the axilla or the supraclavicular fossa. Workup for a recurrence should also be undertaken for patients who present with lymphedema or a brachial plexopathy. When a recurrence is suspected, a core biopsy should be obtained to confirm the diagnosis and to evaluate hormone and HER2 receptor status. In addition, a metastatic workup should be performed. The 5-year survival rate for patients based on site of recurrence is 52% for chest wall alone, 50% for axilla alone, 28% for supraclavicular nodes alone, 28% for chest wall plus axilla, and 7% when both the supraclavicular nodes and chest wall/axilla are involved.⁴⁴² The subsequent treatment plan for patients with recurrent breast cancer is complex and requires a multidisciplinary team.

After BCT, the primary risk factors for recurrence are the use of radiation therapy and pathologic margin status. When an ipsilateral breast cancer is identified, it is important to determine whether this is indeed a true recurrence versus a second primary cancer; a true recurrence is often found within the primary tumor site or the boost volume of the treated breast. Unlike postmastectomy recurrences, which are commonly detected on physical examination, post-BCT recurrences are often identified by surveillance mammography. However, it is important to note that any physical examination changes that occur more than 1 year after completion of radiation therapy warrant further workup, even in the presence of a normal mammogram. In this setting, consideration should be made for MRI and biopsy. For any recurrent disease, biopsy is obtained to confirm diagnosis and tumor receptor status, followed by a complete metastatic staging workup. In the absence of metastatic disease, the standard approach to a local recurrence after BCT is a mastectomy, with most patients surviving at least 10 years.⁴⁴³ In the setting of more advanced recurrent disease, such as that associated with skin involvement or inflammatory changes of the skin, systemic therapy may need to be considered prior to mastectomy. The decision to proceed with axillary restaging should be considered by a multidisciplinary team. Furthermore, the management of regional recurrence after BCT is complex and should be planned with a multidisciplinary approach.

Paget Disease of the Breast

Although the presentation of breast cancer is commonly associated with a mass or a mammographic abnormality, it must be considered in the setting of chronic nipple ulceration. PDB was first noted by Sir James Paget in 1874 when he described 15 women with chronic nipple ulcerations who then developed cancer of the involved breast within 2 years.⁴⁴⁴ The hallmark of Paget disease is a scaly, raw, vesicular, or ulcerated lesion that begins on the nipple and then spreads to the areola (Fig. 74-27). This is often a

unilateral process and can be associated with bloody nipple discharge. Symptoms that can occur prior to the development of clinically apparent disease include pain, burning, and pruritus. PDB is a rare disease accounting for only 1% to 3% of new cases of breast cancer in females in the United States.

Figure 74-27. Paget disease of the nipple. Depigmentation and desquamation of the nipple and areola are evident.

The diagnostic workup of PDB is to first establish the diagnosis and then to identify the underlying breast cancer that is present in 85% to 88% of cases, despite often not being associated with a breast mass or a mammographic abnormality.⁴⁴⁵ Full-thickness wedge or punch biopsy of the nipple should be performed. PDB is characterized histologically by the presence of large cells with prominent nucleoli and a pale cytoplasm (Paget cells) occurring singly or in small groups within the epidermis of the nipple. Other characteristics of Paget cells include the presence of low-molecular-weight cytokeratins such as CK7. Approximately 50% of PDB cases express hormone receptors and between 70% and 90% of cases overexpress HER2.

For patients with PDB, a physical examination including bilateral breast examination and mammography should be performed to help identify the underlying breast cancer. Approximately one-half of patients with PDB will have an associated mammographic abnormality. Interestingly, these abnormalities can occur distant from the nipple areolar complex. If no palpable masses are found and mammography is normal, there is a greater likelihood of DCIS than an invasive cancer.⁴⁴⁶ If mammography and breast imaging fail to locate disease, then a MRI can be obtained, recognizing that although it is highly sensitive it is not highly specific. As such, MRI-detected lesions should be biopsied to confirm the diagnosis of a breast cancer.

The treatment of PDB is either a mastectomy or breast-conserving therapy, which includes a partial mastectomy and whole breast radiation therapy. Breast-conserving surgery includes resection of the nipple–areola complex and the underlying cancer with negative margins obtained (central lumpectomy). Given that the nipple–areola complex is removed, some women may consider this cosmetically unacceptable. Evaluation and treatment of the axilla is dependent on the underlying cancer identified. Adjuvant systemic therapy is also determined by the involved breast cancer.

Breast Sarcomas

Breast sarcomas are rare, accounting for less than 1% of all breast malignancies, characterized by its derivation from the connective tissue within the breast.⁴⁴⁷ It is a heterogeneous disease comprising multiple histologic subtypes including fibrosarcoma (24%), angiosarcoma (24%), undifferentiated pleomorphic sarcoma (24%), myxofibrosarcoma (12%), leiomyosarcoma (8%), hemangiopericytoma (4%), and osteosarcoma (4%).⁴⁴⁸ Primary breast sarcomas can result from genetic conditions such as with the *TP53* mutation (Li–Fraumeni syndrome which is characterized by breast sarcoma, leukemia, and adrenal cortical carcinoma), familial adenomatous polyposis and its variants, and with neurofibromatosis type 1.⁴⁴⁸ Although the causative factor for primary disease is often not known, risk factors for secondary breast sarcomas include ionizing radiation,⁴⁴⁹ conditions causing chronic lymphedema (Stewart–Treves syndrome),⁴⁵⁰ chemicals such as arsenic compounds and vinyl chloride, and with immunosuppression such as with HIV.⁴⁴⁸

A breast sarcoma often presents as a firm, large, unilateral, and painless mass. Mammographic findings are commonly nonspecific with no associated calcifications or spiculations, presenting as noncalcified oval masses with indistinct margins or can even be associated with a normal mammogram.⁴⁵¹ Core biopsy is recommended to confirm the diagnosis. Given that the biology and prognosis differs significantly from invasive breast cancers, breast sarcomas are staged using the

American Joint Committee on Cancer (AJCC)/International Union Against Cancer system for sarcomas arising from other sites.⁴⁵² As most breast sarcomas do not spread through the lymphatic system, even in the presence of large tumors, the lymph nodes are negative for disease. The primary site for metastases is the lung and as such chest CT should be obtained for all newly diagnosed patients.⁴⁵³

Phyllodes Tumor

Phyllodes tumors are uncommon (<0.5% of all breast malignancies) fibroepithelial breast tumors first described by Johannes Muller in 1838 as *cystosarcoma phyllodes*.⁴⁵⁴ Given that these tumors often do not have cystic components and are not true sarcomas, they are now referred to simply as phyllodes tumors (Fig. 74-28). The malignant potential of phyllodes tumors differs widely, with some behaving like fibroadenomas and others that can degenerate histologically into sarcomatous lesions and metastasize distantly. As such, they are histologically classified as benign (50%), borderline (25%), or malignant (25%) based upon the degree of stromal cellularity and atypia, mitotic rate, and the presence or absence of stromal overgrowth and infiltrative margins. Risk factors for phyllodes tumors are not known, aside from their association with Li-Fraumeni syndrome.⁴⁵⁵

Patients with phyllodes tumors present with a smooth, multinodular, well-demarcated, firm mass that is both mobile and painless. The average tumor size is 4 to 7 cm. Although palpable axillary lymphadenopathy can be found in up to 20% of patients, lymph node involvement is rare.⁴⁵⁶ Imaging is notable for a smooth multilobulated mass that resembles a fibroadenoma. Core needle biopsy is recommended for diagnosis. However, it has a false-negative rate of 25% to 30%.^{457,458} As such, in the presence of a rapidly enlarging mass, excisional biopsy should be performed.

Figure 74-28. Breast asymmetry resulting from a benign phyllodes tumor. Skin changes are caused by pressure necrosis.

The treatment of all phyllodes tumors is wide excision to achieve negative histologic margins, with a goal of 1 cm. Even large tumors can be treated with breast-conserving surgery without compromising cancer-specific survival. Lymph node involvement is also very rare; in the SEER database, only 8 of 498 women had involved nodes.⁴⁵⁹ As such, most surgeons do not routinely perform SLNB for phyllodes tumors. The use of adjuvant radiation therapy and chemotherapy is controversial; however, in the setting of a large borderline or malignant phyllodes tumor, these treatments should be considered. If systemic therapy for malignant phyllodes tumor is undertaken, it is based on guidelines for treating sarcomas. Similar to breast sarcomas, malignant phyllodes tumors can metastasize to the lungs and as such patients should undergo chest x-ray every 6 months for 2 years and then annually. Unfortunately, once metastasis develops, the mean overall survival is 30 months.⁴⁶⁰

Chapter 75

Thyroid Gland

David T. Hughes and Paul G. Gauger

Key Points

- 1 The tubercle of Zuckerkandl is an anatomic feature of the thyroid that helps facilitate identification of the recurrent laryngeal nerve (RLN) and the superior parathyroid gland.
 - 2 A nonrecurrent right laryngeal nerve is most commonly due to anomalous origin of the right subclavian artery from the distal aortic arch which then passes posterior to the esophagus (arteria lusoria); a left non-RLN is rare and due to situs inversus.
 - 3 Ultrasound is the imaging procedure of choice for nodular thyroid disease, and surgeon-performed ultrasound helps facilitate operative planning.
 - 4 The Bethesda Classification System for Thyroid FNA can guide further management of thyroid nodules.
 - 5 Additional thyroid resection or adjuvant treatment with radioiodine is seldom required for an incidental papillary microcarcinoma (<1 cm) found in the surgical specimen.
 - 6 Molecular markers including BRAF, RET, and RAS can aid in the diagnosis of thyroid cancer on fine-needle biopsy and in the management of thyroid cancer.
 - 7 Genotype/phenotype correlation using the specific RET protooncogene mutation identified in each patient/family can help determine the appropriate age for prophylactic thyroidectomy in patients with hereditary medullary thyroid carcinoma.
 - 8 Lymphoma of the thyroid or anaplastic thyroid cancer should be considered in the hypothyroid patient who experiences rapid growth of the thyroid.
 - 9 Advantages of total thyroidectomy over thyroid lobectomy for differentiated thyroid carcinoma include (a) removal of multifocal intrathyroidal tumors; (b) facilitation of radioiodine imaging and ablation for residual, regional, or metastatic disease; and (c) use of serum thyroglobulin as a sensitive marker of persistent or recurrent disease.
 - 10 Therapeutic, compartment-based lymph node dissection is indicated for patients with evidence of lymph node metastasis in thyroid cancer.
-

The broad indications for thyroidectomy include hyperthyroidism, thyroid nodularity, thyroid goiter, Graves disease, thyroid cancer, and prophylaxis in multiple endocrine neoplasia type 2. Understanding of the embryology, anatomy, physiology, and relevant pharmacology of thyroid disease and precise surgical technique and careful attention to detail are necessary to prevent complications of thyroid surgery.

EMBRYOLOGY AND SURGICAL IMPLICATIONS

Developmental Embryology

The thyroid is mostly derived of endoderm from the ventral embryologic digestive tract and is the first endocrine gland to develop. A midline diverticulum arises in the area of the foramen cecum at the base of the tongue at approximately 4 weeks of gestation. The tissue descends as the median thyroid component and ultimately becomes the isthmus and the majority of each lateral lobe. The foramen cecum ruptures and resorbs during week 6 of gestational age, leaving behind a regressive fibrous thyroglossal duct (including the portion associated with the central hyoid bone). The distal end of the thyroglossal duct tract persists as a recognizable pyramidal lobe attached to the isthmus in about 30% to 50% of individuals. The lateral thyroid components develop from the caudal pharyngeal endoderm (with contribution from the fourth and fifth branchial pouches) and arise later in development than the

median component.¹ The lateral components become increasingly removed from the pharynx, leaving a tapering connection on each side, which eventually detaches. The residual posterolateral projection from the lateral thyroid component is known as the tubercle of Zuckerkandl. Because of its branchial pouch origin, the lateral thyroid component is closely associated with the superior parathyroid anlage (from the fourth pouch). The lateral components contain C cells (from neural crest origin) which migrate into the superolateral portion of the lobes and eventually secrete calcitonin. The unified thyroid begins to differentiate into thyroid follicles between 8 and 11 weeks. Thyroid hormone production begins on a cellular level by the third month of gestation when iodine trapping occurs.

Congenital Abnormalities

A lingual thyroid gland is an uncommon developmental malformation of thyroid tissue erupting from the base of the tongue due to failure of the median thyroid component to descend from the foramen cecum. Treatment of lingual thyroid can include exogenous thyroid hormone to suppress thyroid-stimulating hormone (TSH), radioiodine ablation or surgical excision. Thyroglossal duct cysts occur in the midline of the neck along the path of descent of the median thyroid component. They may occur from the base of the tongue to the low central neck, although most are located just inferior to the hyoid bone. Although they are often discovered during infancy and childhood, it is not uncommon for them to present in adulthood – discovered either because of mass effect or infection. Elevation of the mass with protrusion of the tongue is very suggestive of a thyroglossal duct cyst. Resection of a thyroglossal duct cyst involves excision of the entire thyroglossal duct, the cyst, and the tract as it courses through the central portion of the hyoid bone (Sistrunk procedure). The epithelial lining usually contains some thyroid cells and thyroid carcinomas (usually of papillary type) can arise along the thyroglossal duct tract.

Ectopic thyroid tissue can be found in other areas of the central cervical compartment and the mediastinum. These can be extrathyroidal nodules associated with multinodular goiters or embryologic rests of thyroid tissue along the path of caudal migration.² Historically, the concept of *lateral aberrant thyroid* tissue was used to describe follicular thyroid tissue in the carotid sheath or the lateral compartments of the neck; however, it is now generally agreed that this cannot occur as an embryologic abnormality and rather this represents a regional nodal metastasis of differentiated thyroid cancer (DTC).

ANATOMY AND SURGICAL IMPLICATIONS

A normal thyroid gland weighs between 15 and 20 g. The thyroid isthmus is approximately 1 to 2 cm in transverse and vertical dimensions and normally overlies the trachea from just below the cricoid cartilage to the fourth or fifth tracheal ring. The lateral lobes lie adjacent to the thyroid cartilage and cricothyroid muscle as well as the lateral trachea and a portion of the lateral esophagus on each side. The two lobes are roughly conical and normally measure ~5 cm in craniocaudal and 2 to 3 cm in mediolateral and anteroposterior dimensions.

Muscular, Fascial, and Airway Relationships

The thyroid lies in the central compartment of the neck bordered by the contents of the carotid sheath on each side. The anterolateral surface is covered by the sternothyroid muscles, which do not completely meet in the midline above the level of the isthmus. Superficial to the sternothyroid muscles are the sternohyoid muscles that meet at the median raphe which is typically split during thyroidectomy. These muscles are innervated on the inferolateral aspect by the ansa cervicalis (ansa hypoglossi). The thyroid is invested in a thin layer of connective tissue that is an expansion of the pretracheal fascia (often called the “thyroid sheath”). The sheath is not to be confused with the thyroid capsule, which is more integral to the gland itself. The plane between the capsule and the sheath is usually easy to develop as the thyroid is mobilized away from surrounding structures. Especially near the superior portion of the thyroid, the sheath defines a coronal plane that, when opened, exposes the potential space between the pharynx/esophagus and the cervical vertebral bodies. The sheath is condensed as the anterior suspensory ligament above the isthmus. The sheath also attaches the posterior surface of the thyroid gland to the tracheal rings and is condensed posteromedially into the ligament of Berry on each side. The ligament of Berry is a firm attachment to the trachea near the cricothyroid space and is often intimately associated with the recurrent laryngeal nerve (RLN) near its insertion at

the cricopharyngeus muscle. The RLN is most vulnerable to iatrogenic injury when dividing the ligament of Berry.

Vascular Relationships

The thyroid gland has a very high blood flow index per tissue mass and receives its arterial supply from a paired system of superior thyroid arteries (originating as the first branch of the external carotid arteries) and inferior thyroid arteries (originating from the thyrocervical trunks). The superior artery courses along the inferior pharyngeal constrictor muscle group and branches near the tip of the superior pole of the thyroid, usually into at least an anterior and posterior branch. The inferior thyroid artery (ITA) courses behind the carotid artery and then crosses medially to meet the thyroid lobe just below the ligament of Berry near the tracheoesophageal groove. The ITA has multiple branches that course in a plane between the sheath and the capsule of the gland. The relationship of the ITA to the RLN is an important landmark and the specific relationship between the ITA and the RLN (anterior, posterior, or interdigitated) may be variable and caution should be taken in ligation of the ITA branches during thyroidectomy. Occasionally, an arteria thyroidea ima arises from the aorta or innominate artery and courses anterior to the trachea to directly serve the inferior portion of the thyroid gland.

Venous drainage of the thyroid is by a widely anastomosing system that condenses into three main trunks. The superior thyroid veins course adjacent to the superior thyroid arteries but empty into the internal jugular vein at the level of the carotid bifurcation. Middle thyroid veins are present in more than half of patients and drain laterally to the internal jugular vein. These veins are divided early in the course of mobilizing the thyroid lobe. In tracing a vessel laterally, if it passes anterior to the carotid artery, it is a middle thyroid vein, whereas if it passes posterior to the carotid, it is the ITA. The inferior thyroid veins form nearly all of the vascular connections found at the inferior poles of the thyroid lobes and are situated anterior to the RLN. The number and configuration of these veins can be quite variable, but in general they descend along the course of the thyrothymic tract to drain into the ipsilateral brachiocephalic vein.

Neurologic Relationships

1 Two nerves have critical importance during thyroidectomy: the recurrent laryngeal nerve (RLN) (also known as the inferior laryngeal nerve) and the external branch of the superior laryngeal nerve (EBSLN). The right RLN arises from the vagus at the level of the subclavian artery and passes (recurs) around the posterior aspect of the artery before ascending into the central compartment. The right RLN takes an oblique course in the central neck and may be 1 to 2 cm lateral to the trachea low in the central neck before traveling toward its entry point at the cricothyroid. The left RLN arises from the vagus nerve as it crosses the aortic arch posterior to the ligamentum arteriosum. It passes inferior and medial to the arch and ascends to the larynx in the tracheoesophageal groove along a course that is typically linear and more vertical than the right RLN. The RLN often lies immediately posterolateral to the ligament of Berry, but it is not infrequent that it can be embedded in the fibrous connections of the ligament itself, especially the anterior branch if the RLN bifurcates outside the larynx. In a standard anatomic relationship, the tubercle of Zuckerkandl lies immediately lateral to and covers the RLN (Fig. 75-1). An uncommon, but high-risk, anatomic arrangement occurs when the RLN is found lateral to the tubercle of Zuckerkandl (Fig. 75-2). If the surgeon is unaware of this possibility (which may exist when the tubercle has undergone nodular enlargement), the nerve is subject to iatrogenic injury.³ Up to 34% of RLNs will bifurcate proximal to the inferior border of the cricoid cartilage with the anterior branch containing the motor fibers and the posterior branch containing sensory fibers.⁴ Injury to these branches can lead to hoarseness and aspiration due to motor and sensory dysfunction respectively, manifesting as hoarseness and/or aspiration.

Figure 75-1. The standard anatomic relationship whereby the recurrent laryngeal nerve (RLN) passes medial to the tubercle of Zuckerkandl before its insertion into the cricothyroid interval.

Figure 75-2. The uncommon but high-risk anatomic variation where the recurrent laryngeal nerve (RLN) courses lateral to the tubercle of Zuckerkindl, which is often enlarged. The nerve is encountered much earlier in the dissection required for thyroidectomy and is at risk of being misidentified as a vascular structure.

2 It is critical to be aware of the occasional non-RLN (also called a “direct” laryngeal nerve). This anomaly results from abnormal embryonic development of the aortic arch. The anomaly is more common on the right (approximately 0.5% to 0.7%) than on the left (approximately 0.04%).⁵ On the right, a nonrecurrent nerve is the consequence of the formation of the arteria lusoria vascular abnormality, in which the innominate artery is absent and the right common carotid and right subclavian arteries originate directly from the arch. The right subclavian artery arises as a branch of the aortic arch distal to the left subclavian and takes a retroesophageal course. This anomaly can produce dysphagia due to compression of the esophagus between the posterior trachea and the subclavian artery termed *dysphagia lusoria*. A nonrecurrent left RLN requires a right-sided aortic arch (as occurs in situs inversus viscerum), the origin of the left subclavian artery abnormally sited on the aortic arch, and the displacement of the ligamentum arteriosum to the right and thus is a rarely found anomaly.

The superior laryngeal nerve (SLN) arises from the vagus at the nodose ganglion near the base of the skull and descends along the course of the internal carotid artery. At the level of the hyoid bone, it bifurcates into the internal branch (which enters the larynx at the thyrohyoid membrane to provide sensory innervation to the superior larynx) and the external branch (which provides motor innervation to the cricothyroid muscle which contributes to variation in voice pitch and projection). The external branch has a variable course in relation to the inferior pharyngeal constrictor muscle and the branches of the superior thyroid artery which makes it vulnerable to iatrogenic injury. The Cernea classification of the anatomic variations of the SLN are depicted in Figure 75-3.⁶

Lymphatic Relationships

Lymph flows in multiple directions through a rich plexus surrounding the thyroid. The thyroid gland has intracapsular lymph channels, which provide some communication between lobes across the isthmus. The central compartment (level VI) nodal basin is comprised of the pretracheal and paratracheal nodes and those along the RLNs between the carotid sheaths laterally and extends from the hyoid bone cranially and to the level of the innominate artery caudally.⁷ Within the anterior suspensory ligament near the pyramidal lobe is a small group of midline prelaryngeal lymph nodes known as the Delphian nodes. The lateral cervical nodal basins include the upper jugular (level II), midjugular (level III), and lower jugular (level IV) lymph nodes as well as the posterior triangle lymph nodes (level V) (Fig. 75-4). Thyroid cancers with regional lymph node metastases tend to involve level VI before involving levels II, III, IV, and ultimately V.⁸ Level I (submental) and level VII (superior mediastinal) involvement is less common but can occur. Documented cases of “skip” metastases directly to the lateral compartment with no level VI involvement have been reported but are atypical.⁹

Figure 75-3. Cernea classification of the anatomic relationships between the external branch of the superior laryngeal nerve

(EBSLN), the superior pole of the thyroid, and the superior thyroid artery. With type 1 anatomy, the nerve crosses the superior thyroid vessels 1 cm or more above the superior thyroid pole. With type 2 anatomy, the nerve crosses the vessels less than 1 cm above (type 2a) or even below (type 2b) the superior pole. Type 2 variants are the most vulnerable to iatrogenic injury.

Parathyroid Relationships

Parathyroid glands are encountered during thyroidectomy by virtue of their association with the thyroid gland, however, ectopic parathyroid glands will typically not be encountered. The superior parathyroid gland is usually located in a relatively constant area largely because of the embryologic association between the lateral thyroid component and the superior parathyroid anlage (both associated with the fourth branchial pouch). The tubercle of Zuckerkandl is anatomically associated with the position of the superior parathyroid gland as well as the RLN. In relation to the point at which the RLN intersects the ITA, a 2-cm circumscribed area on the cranial aspect will often contain the superior parathyroid gland. It may also be found tucked posterior to the ITA or even posteromedial to the superior thyroid pole. There is an 80% chance that a superior parathyroid gland will be found in a position similar to its contralateral partner.

Figure 75-4. Classification scheme for regional lymph node basins in the neck.

The location of the inferior parathyroid gland is more variable. It may be found on the anterior aspect of the inferior thyroid pole or on the inferolateral aspect. It may also be in the triangular region caudal to the ITA and anterior to the RLN. If it is not in these locations, it is often embedded in fat and thymic tissue within the thyrothymic tract. The symmetry of inferior parathyroid glands from side to side is approximately 70%.

THYROID PHYSIOLOGY

Production of Thyroid Hormones

The thyroid gland produces thyroxine (T_4), triiodothyronine (T_3), and calcitonin under regulatory mechanisms. The production of thyroid hormone by the follicular cells is ultimately orchestrated by the anterior pituitary gland through its secretion of thyrotropin (TSH) to maintain a euthyroid state through a feedback loop. The production of thyroid hormone by the follicular cell (thyrocyte) is depicted in [Figure 75-5](#). Approximately 100 to 150 μg of daily dietary iodide is required for normal thyroid hormone synthesis to occur. In most developed regions of the world, daily intake from iodine-containing foods is usually far in excess of this requirement and the kidneys excrete the iodide not utilized by the thyroid. The active uptake of iodide in the thyroid occurs on the basolateral aspect of the

follicular cells through a Na^+/I^- symporter which is mediated by a Na^+/K^+ -adenosine triphosphatase (ATPase) pump. Both TSH and the circulating concentration of iodide influence this symporter system. TSH acts upon the thyroid gland to regulate the synthesis of thyroglobulin (Tg), the active uptake of iodide, its incorporation with tyrosine (an oxidative reaction catalyzed by thyroid peroxidase [TPO]), the subsequent production of T_4 and T_3 (and their storage bound to Tg in the colloid component of the gland), and ultimately the release of both T_4 and T_3 into the circulation. Hormone release is an active process of micropinocytosis that involves resorption of the bound Tg from the colloid compartment into the follicular cell where enzymatic degradation releases T_4 and T_3 , which is released from the basal portion of the cell into the circulation. T_4 is produced in preference to T_3 in the thyroid gland by a ratio of approximately 13:1 in normal states. T_4 has a relatively weak biologic action, so peripheral conversion to the more active T_3 hormone is required. Most of this takes place in the plasma and liver by type 1 deiodinase enzymes. All of the T_4 in the circulation is derived from the thyroid, whereas less than 20% of T_3 in the circulation is from the thyroid, the majority being produced enzymatically from monodeiodination of T_4 in the periphery. In circulation, most thyroid hormone (>99% of both T_4 and T_3) is bound to proteins such as thyroxine-binding globulin (TBG), albumin, and thyroxine-binding prealbumin. Protein-bound thyroid hormones are considered biologically inert because they do not enter cells until they are released from proteins to circulate in the very small free fraction. The half-life of T_4 is approximately 7 days, whereas the half-life of T_3 is much shorter – on the order of 8 to 12 hours.

Figure 75-5. Thyroid hormone metabolism. Thyroxine (T_4) and Triiodothyronine (T_3) are produced by the thyroid follicular cell in a complex biochemical pathway. It is dependent on the movement of circulating iodide through the follicular cell and into the intracellular colloid space. T_3 and T_4 are then bound to Thyroglobulin (Tg) for eventual transport back through the follicular cell to be released into the intravascular space.

Action of Thyroid Hormones

Thyroid hormones have many effects on various body tissues. The peripheral conversion from T_4 to T_3 increases the binding affinity of thyroid hormone for the nuclear thyroid receptor protein at least 10-fold. T_3 acts within the nucleus of peripheral tissues via four T_3 nuclear receptor subtypes to activate T_3 -regulated gene transcription. Ultimately, the physiologic actions of thyroid hormone relate to growth, differentiation, calorogenesis, and TSH suppression.

Calcitonin is a 32-amino-acid polypeptide that is physiologically effective in many other species, but in humans it is apparently less important. Although exogenous calcitonin may have a therapeutic effect, endogenous calcitonin secretion rarely results in an impact on serum calcium levels which are primarily

mediated by parathyroid hormone.

RELEVANT LABORATORY TESTS

An understanding of the normal relationship between free T_4 (FT_4) levels and TSH levels is critical for appropriate interpretation of thyroid function tests. Thyroid function can be determined directly, by measuring FT_4 levels, or indirectly, by measuring TSH. If TSH is to be used as the primary indicator of thyroid dysfunction, an intact hypothalamic–pituitary axis is required. Normally, a log/linear inverse relationship between TSH and FT_4 is defined by the negative feedback inhibition of TSH secretion by circulating thyroxine levels, therefore minor perturbations of FT_3 and FT_4 lead to wide suppression or elevation of TSH levels. High TSH and low T_4 and T_3 levels are indicative of hypothyroidism and low TSH and high T_4 and T_3 levels are characteristic of hyperthyroidism. It is likely that each individual has a genetically determined FT_4 set point. Early subtle deviation from that set point will cause amplified changes in the TSH value, thus making TSH a very sensitive and clinically useful early indicator of thyroid dysfunction.

Thyroid-Stimulating Hormone (Thyrotropin)

As the sensitivity and specificity of current TSH assays are quite high, the indirect approach of measuring TSH levels is the most sensitive method for detecting thyroid dysfunction. The inverse relationship between TSH and FT_4 also dictates that small alterations in FT_4 will lead to a larger response in TSH, thus adding further support to this strategy. Modern methods are generally based on immunometric assays and are able to achieve a sensitivity of 0.02 mIU/L or less. At present, the normal range for TSH is considered to be 0.45 to 4.12 mIU/L.¹⁰ The target range of TSH for patients treated with levothyroxine (LT_4) for hypothyroidism during pregnancy or after thyroidectomy have a lower target of 0.45 to 2.5–3.5 mIU/L.

Free Thyroxine and Free Triiodothyronine

Technically, it is easier to measure the total (free + protein-bound) hormone levels (measured at nanomolar levels) as compared to the very small free hormone concentrations (measured at picomolar ranges). Because T_4 is more tightly protein bound than T_3 , it is less bioavailable and, consequently, very difficult to measure directly. Measuring FT_4 or free triiodothyronine (FT_3) in preference to total thyroxine (TT_4) or total triiodothyronine (TT_3) improves the ability to detect thyroid dysfunction in the presence of thyroid hormone–binding abnormalities, which are relatively common. For example, some common drugs such as phenytoin, carbamazepine, furosemide, and aspirin may compete with thyroid hormone for binding to serum proteins.

Total Thyroxine and Total Triiodothyronine

Total hormone assays require an inhibitor to block or displace the hormone from its binding proteins. This factor, along with large sample dilution, allows binding of the hormone to the antibody reagent. Because of the 10-fold lower concentrations of T_3 in the serum, the TT_3 assay requires even greater sensitivity and precision. Abnormal TT_4 and TT_3 measurements are more commonly caused by variance in the binding capacity of serum protein rather than true thyroid dysfunction.

Thyroglobulin

The primary clinical use of thyroglobulin (Tg) measurement is as a tumor marker, which serves as an index of the amount of DTC present (assuming that all normal thyroid tissue has been removed with total thyroidectomy with or without radioiodine ablation). Tg is measured in the serum by radioimmunoassay methods or by immunometric assays. The latter is more susceptible to competitive interference by thyroglobulin autoantibodies (TgAbs), which cause an artifactual decrease in the measured levels. TgAbs may be present in approximately 3% to 10% of the general population, 20% of patients with differentiated thyroid carcinoma and 80% to 100% of patients with Hashimoto thyroiditis. Sensitive quantitative TgAb determination is a critical accompaniment to serum Tg measurement because the presence of these antibodies prevents the use of Tg as an accurate tumor marker for thyroid cancer. The particular assay utilized must be sensitive enough to detect Tg levels at the lower end of the reference range (1 to 3 $\mu\text{g/L}$). Elevated TSH levels typically stimulate higher levels of Tg, therefore

interpretation of Tg levels require TSH determination at the time of measurement.

Thyroid Autoantibodies

Thyroid peroxidase autoantibodies (anti-TPOab) and antithyroglobulin autoantibodies (anti-Tgab) are elevated in Hashimoto thyroiditis. A significant fraction (up to 12%) of people with no apparent thyroid disorder may also have positive anti-TPOab titers. TSH receptor autoantibodies (anti-TSHRab) are heterogeneous and may mimic the action of TSH to cause hyperthyroidism as in Graves disease or, conversely, may block the action of TSH and cause hypothyroidism as occurs in neonates of a mother with thyroid autoantibodies. Thyroid-stimulating immunoglobulin (TSI) elevations suggest graves disease.

Calcitonin

Basal calcitonin levels are generally less than 16 pg/mL for healthy people and for nearly all patients with thyroid disease, other than medullary thyroid carcinoma (MTC). Therefore, calcitonin serves as a very specific tumor marker for MTC. Basal calcitonin levels are useful for diagnosis and observation of MTC patients.

THYROID IMAGING TECHNIQUES

Ultrasound (US) is the most useful imaging test for evaluation of structural thyroid pathology. Various other imaging modalities may be useful in specific circumstances.

Ultrasonography

3 US is the imaging technique of choice to evaluate the thyroid gland and its surrounding structures. It is best performed using a high-frequency “small parts” probe (7.5 to 15 mHz). As with any imaging technique that depends on individual performance of the test, a user-dependent factor exists. US can be especially useful when performed by the surgeon and allows appropriate preoperative planning. US is the most sensitive and specific technique to determine the size, number, and distribution of thyroid nodules. US often detects very small, subtle nodules that are not otherwise clinically evident. Studied prospectively, the prevalence of asymptomatic thyroid nodules (thyroid incidentalomas) detected by ultrasonography is approximately 67%, whereas physical examination identifies thyroid nodules in approximately 5% to 8%.¹¹ Hyperechoic nodules are often benign, whereas thyroid malignancies, regardless of cell type, are often hypoechoic. Irregular margins between the nodule and surrounding tissues raise concern for malignancy. An anechoic rim around the nodule is referred to as a “halo” sign and is more likely to be associated with a benign nodule (Figure 75-6A). Larger macrocalcifications with posterior acoustic shadowing are usually indicative of chronicity and are more likely associated with a benign nodule, whereas subtle microcalcifications, which cause a “twinkling” or “stars in the sky” effect when the transducer is moved across the nodule, are correlated with malignancy (Figure 75-6B). In practical terms, selective FNA biopsy is indicated for nodules greater than 1–1.5 cm, those with concerning US features, or those that have increased in size under serial US measurement.¹² Because US can detect nodules at a preclinical stage, it follows that proper perspective about the significance or insignificance of these nodules must be maintained. US has an important role in the preoperative staging and postoperative follow-up of patients with differentiated thyroid carcinoma and evaluation of the cervical lymph nodes with ultrasound should be considered mandatory prior to surgery. In experienced hands, it is a very sensitive technique for detecting abnormally enlarged lymph nodes or tumor recurrence within the thyroid bed, and for guiding subsequent confirmatory biopsy. It is especially important for identifying sites of recurrent thyroid cancer in those patients with negative radioactive iodine (RAI) scans or in dedifferentiated tumors that are no longer iodine avid.

Figure 75-6. Ultrasound images of the right thyroid lobe. (A) benign thyroid nodule with isoechoic solid architecture and hypoechoic halo and (B) papillary thyroid carcinoma with microcalcifications and irregular border. C, carotid artery; J, internal jugular vein; T, trachea.

Nuclear Medicine Imaging

Radionuclide imaging provides specific information regarding the functional characteristics of the thyroid usually in the setting of hyperthyroidism; however, it provides little anatomic detail. Nuclear imaging for thyroid nodules is typically only helpful in determining if the etiology of hyperthyroidism in a nodular thyroid is due to a hyperfunctional nodule(s) or diffuse hyperplasia.

Technetium Pertechnetate ^{99m}Tc Scintigraphy

^{99m}Tc pertechnetate is the radionuclide most commonly available for thyroid imaging. The ^{99m}Tc pertechnetate component is actively trapped by functional thyroid cells in a manner similar to iodine but is not organified or stored in the thyroid. The isotope emits gamma (γ) radiation (the mechanism of scintigraphic imaging) and very small amounts of other types of radiation. Because the thyroid rapidly absorbs the injected ^{99m}Tc pertechnetate, imaging can occur early after administration and an entire study may take only an hour. A normal result demonstrates equal distribution bilaterally. Abnormal results include either concentration of the tracer in the region of a known nodule indicating an area of hyperfunction or, conversely, an area of photopenia (the “cold nodule”) indicating a region of hypofunction. Before the era of fine-needle aspiration (FNA) biopsy, photopenic nodules increased the concern for potential malignancy; however, currently nuclear imaging is typically only used to determine the etiology of hyperthyroidism in a nodular or enlarged thyroid and should not be used to determine the oncologic risk of thyroid nodules.

^{123}I Iodine Scintigraphy

Because ^{123}I is trapped and organified by the thyroid gland, it can better indicate the functional characteristics of thyroid tissue. ^{123}I emits x-rays, some β particles, and γ rays. It has a short half-life of about 13 hours. After administration of an oral dose, the thyroid absorbs sufficient isotope to allow imaging by 4 hours. Images are also obtained at 24 hours, and the total fraction of dose retained by the thyroid can then be calculated as the 24-hour radioactive iodine uptake (RAIU).

^{131}I Iodine Scintigraphy

^{131}I sodium iodide concentrates in the thyroid by the same mechanism as ^{123}I , but has a much longer half-life (about 8 days) and emits much more β radiation along with γ radiation at a range that is suboptimal for clear image creation. However, because of its long half-life and thorough clearance from background tissues, it remains the isotope of choice for imaging of patients with differentiated thyroid carcinoma. Treatment or ablation of residual or metastatic carcinoma (largely by the effect of β irradiation) is accomplished with larger doses of ^{131}I (typically 30 to 150 mCi) than is required for diagnostic imaging (typically 1 to 5 mCi).

Positron Emission Tomography

^{18}F fluorodeoxyglucose positron emission tomography (PET) scanning with three-dimensional tomographic reconstruction can be very helpful in imaging thyroid carcinomas, and allows anatomic and functional evaluation. Because of the expense and the inconsistent insurance coverage, usage is currently limited to unusual circumstances such as recurrent thyroid malignancy that is otherwise occult most commonly due to loss of iodine uptake and subsequent negative ^{131}I scans. The sensitivity of PET in recurrent, radioiodine-resistant thyroid carcinomas is approximately 60% to 70% with some studies

suggesting improved detection rates with TSH-stimulation or recombinant human TSH (rhTSH).¹³ PET scanning is frequently used in the evaluation of other solid malignancies and occult thyroid carcinomas are discovered in 2% to 3%.¹⁴ Incidentally discovered thyroid nodules which are focally PET-avid are malignant in 30% to 35% and require evaluation with US and FNA biopsy.^{15,16}

Figure 75-7. Example of a multinodular goiter with a large substernal component causing tracheal displacement and compression.

Cross-Sectional Imaging

Computed tomography (CT) scans and magnetic resonance imaging (MRI) scans are useful in certain thyroid disease states after initial US and/or nuclear imaging. CT is particularly useful to determine the extensiveness of invasive thyroid cancer suggested by physical examination findings of fixed nodules, new vocal cord paralysis, or suspicion of tracheal invasion. CT is also useful in assessing for substernal extension and tracheal deviation or compression in large goiters (Fig. 75-7). Finally, cross-sectional imaging is helpful in assessing the degree of nodal involvement in thyroid cancer especially in the low central neck and superior mediastinum, as these compartments are typically not well visualized by cervical US.

FUNCTIONAL DISORDERS AND GENERAL TREATMENT CONSIDERATIONS

Hyperthyroidism

The etiology of hyperthyroidism includes Graves disease, toxic multinodular goiter, solitary toxic adenoma, thyroiditis, TSH-secretion pituitary adenoma and excess of thyroid hormone supplementation. Typical symptoms are heat intolerance, sweating, palpitations, tremor, hyperphagia, thirst, weight loss, and sleep disturbances. Elderly patients can present with muscle wasting, atrial fibrillation, angina pectoris, or congestive heart failure. Regardless of the specific cause, the need to control hyperthyroidism before operation is critical to prevent thyroid crisis (i.e., thyroid storm). Maximal safety is assured with thionamides (methimazole or propothiouracil) combined with beta blockade.¹⁷ Adverse reactions of thionamides include agranulocytosis and hepatic toxicity which can be monitored with white blood cell counts and liver function tests. Titration of thionamides for adequate preoperative blockade with thyroid function tests should rely on T_3 and T_4 levels because TSH levels can remain suppressed for several months even after achievement of normal T_3 and T_4 levels. Doses of beta blockers should continue through the morning of surgery and should be weaned in the postoperative setting.

Graves Disease

Dr. Robert Graves first described Graves disease in the 1830s as a toxic diffuse goiter associated with exophthalmos and palpitations. It is an autoimmune disorder characterized by the presence of thyroid-stimulating autoantibodies with a genetic predisposition and a female predominance (five to seven times greater than males). These antibodies bind to the TSH receptor on follicular cells, stimulate thyroid hormone release, and have a trophic effect on the thyroid. The autoimmune disease process may affect the eyes, causing exophthalmos secondary to inflammatory cell infiltration into the extraocular muscles and orbital connective tissue. Graves ophthalmopathy can lead to changes in visual acuity,

ocular dryness, and proptosis which may be so severe as to require aggressive ophthalmologic treatment in approximately 5% of patients. Graves disease may cause pretibial myxedema which is distinguished from pedal edema by sparing of the ankles. Patients with Graves disease usually have a diffuse goiter, which may be smooth or occasionally irregular. The gland is by nature hypervascular and may occasionally have an audible bruit or palpable thrill in severe cases. T_4 and T_3 levels are increased and TSH levels are suppressed. The uptake of radioiodine (RAI) generally shows a symmetrically enlarged gland with diffuse increased 24-hour uptake.

Three main treatment modalities for Graves disease are medical therapy, radioactive iodine treatment, and thyroidectomy. Selection of therapy depends on age, disease severity, goiter size, and patient preference. Practice patterns differ dramatically across the world, especially regarding the use of radioiodine (it is less common in Europe and especially Japan compared to the United States). The most common initial treatment involves thionamides and often beta blockade. In a small fraction of patients, antithyroid drugs may be the only therapy necessary, but in general, this strategy is considered an impermanent solution as most patients will have persistent hyperthyroidism after cessation of medication. Although the drugs may theoretically be used long term, they are associated with a small but real risk of life-threatening agranulocytosis and liver toxicity. Ultimately, most patients pursue a permanent therapy with RAI or surgery. Treatment with RAI is very effective and has not been associated with secondary risk of development of a new malignancy, yet there is still hesitancy to use this treatment in young children. RAI may take up to 6 months to provide definitive results and thus antithyroid medications must continue during this period. In a small percentage of patients, a second treatment may be necessary. After RAI treatment, 95% of patients become hypothyroid within 10 years and require thyroid hormone replacement. RAI therapy has been occasionally associated with exacerbation of Graves ophthalmopathy, although the effect is ameliorated by corticosteroids and the early addition of LT_4 posttreatment.^{18–20} Because of this concern, patients with severe ophthalmopathy should consider total thyroidectomy instead of RAI to prevent such an exacerbation; however, ultimate resolution of ophthalmopathy is no more likely with surgery.

Surgery for Graves disease has the advantage of rapid correction of the hyperthyroid state. The specific operation has typically been either bilateral subtotal thyroidectomy or total thyroidectomy. Subtotal thyroidectomy attempts to remove enough tissue to resolve the hyperthyroidism but leave enough to maintain euthyroidism, however, Graves disease is dynamic and remissions after subtotal thyroidectomy occurs in approximately 10% of patients at 5 years.²¹ Therefore total thyroidectomy is the preferred operation for treatment of Graves disease with the intention of eliminating the chance of recurrence, but accepting postsurgical hypothyroidism requiring thyroid hormone replacement.

Toxic Multinodular Goiter

The term *toxic multinodular goiter* (MNG) refers to thyrotoxicosis that is caused by a multinodular goiter due to an endemic or nonendemic etiology. H.S. Plummer first distinguished toxic adenomatous goiter from Graves disease. Although the eponym “Plummer disease” now more commonly refers to the patient with a solitary toxic nodule, many clinicians still include toxic MNG under the same historical blanket. Thyrotoxicosis may occur as a progression from euthyroid multinodular goiter that was initially TSH-dependent, which then progressed to a state of autonomy which is not suppressible with LT_4 . Although the cause is clearly distinct, it is possible that some patients included in this diagnostic category actually have Graves disease with nodular degeneration of their diffuse goiter. Patients with toxic MNG, however, are often easily distinguished from those with Graves disease such that the typical patient is a female older than 50 years with a previous history of multinodular goiter. Thyrotoxicosis may be precipitated in an MNG with or without areas of autonomy when an iodide load is provided (Jod-Basedow phenomenon). Historically, public health efforts to iodinate salt or flour in an iodine-deficient population have caused this phenomenon to follow over a period of years. This can occur after exposure to iodinated radiographic contrast media, expectorants, or iodide-containing drugs such as amiodarone.

Hyperthyroidism present in a patient with MNG can involve a wide spectrum of severity such that it is not uncommon for a patient having structural indications for thyroidectomy, such as continued nodular growth, substernal extension or compressive symptoms, in addition to hyperthyroidism. Thyroidectomy or radioiodine treatments are effective treatments for toxic MNG. Radioiodine treatment may require high doses or repeated treatments because of the large goiter size and low radioiodine uptake, however, remains a viable option for patients who are not surgical candidates.¹⁷ Long-term remissions from antithyroid drug treatment are even less common or predictable than in Graves disease

and are not considered a definitive therapy for toxic MNG.²²

Solitary Toxic Adenoma

Patients with thyrotoxicosis and a dominant thyroid nodule may have a toxic adenoma. Nodules usually grow to at least 2 cm in size before hyperthyroidism is clinically evident. As expected, T₃ or T₄ or both are elevated and TSH is suppressed. US typically demonstrates a thyroid nodule with benign US characteristics and FNA is rarely helpful because the incidence of malignancy within these nodules is negligible. Thyroid scintigraphy will demonstrate a single “hot” area corresponding to the known nodule with suppression of the remainder of the thyroid. Treatment options include ¹³¹I RAI therapy or thyroidectomy. RAI is effective in controlling the hyperthyroidism, but depending on nodule size, may leave behind a palpable abnormality. In particular, younger patients with sizable nodules may choose operation. The resection is typically a hemithyroidectomy and the contralateral lobe is often normal and capable of maintaining normal thyroid hormone production in 85% of patients.²³

Hypothyroidism

Primary hypothyroidism can arise from intrinsic thyroid disease, iatrogenic thyroid removal or destruction, and antithyroid drug effects. Secondary hypothyroidism can also occur from failure of thyrotropic function (via TSH) due to pituitary gland disease, removal, or destruction. Rarely, tertiary hypothyroidism can occur with destructive disorders of the hypothalamus via decreased production of thyrotropin-releasing hormone. The most common cause of primary hypothyroidism in adult patients is Hashimoto thyroiditis. In large part, hypothyroidism is straightforward to address with exogenous LT₄ therapy. The role for surgical therapy is limited aside from patients with a structural thyroid disorder associated with underlying hypothyroidism.

Thyroiditis

Inflammatory conditions of the thyroid are a disparate family of conditions that require surgical therapy in the minority of situations. Thyroiditis can be quite prevalent in patients undergoing evaluation for thyroid surgery and a thorough understanding is required to avoid diagnostic and therapeutic misadventures.

Hashimoto Thyroiditis

Also known as chronic thyroiditis, autoimmune thyroiditis, and lymphocytic thyroiditis, this condition was described by Hashimoto in 1912 based on its histologic findings. It affects approximately 10% of the general population, has peak ages from 30 to 60 years and a female-to-male preponderance as high as 9:1. It is clearly an autoimmune condition and there is a moderate genetic predisposition, associated with human leukocyte antigen (HLA)-DR3, -DR5, and -B8. The disease prevalence is increased in iodine-sufficient regions and this may be because immunogenicity of the thyroglobulin molecule increases with the degree of iodination. The histologic changes are characterized by lymphocytic infiltration with fibrosis and germinal centers. Some follicular cells may undergo metaplasia to Hürthle cells. The typical presentation is that of a painless diffuse goiter in a young woman discovered on physical examination with or without associated hypothyroidism. Patients often note a sense of fullness in, or awareness of, the thyroid. When the associated goiter is large, compressive symptoms of dysphagia or dyspnea may occur. The goiter is typically firm and rubbery and slightly “bumpy” with prominent lateral lobes. The US appearance of the thyroid is typically heterogeneous in its echotexture with irregular capsular borders with or without distinct nodules. Nodular disease in a gland affected by Hashimoto disease should be investigated with FNA to rule out coexisting malignancy. Thyroid autoantibody titers are elevated, TPOAb primarily and TgAb secondarily. In approximately 5% of patients, a transient phase of hyperthyroidism, termed “Hashitoxicosis,” occurs at the onset of disease. Following onset, approximately 5% per year will progress to hypothyroidism.²⁴ For the majority of patients, treatment of Hashimoto thyroiditis is limited to LT₄ therapy in those with hypothyroidism. Surgery is indicated in patients with large goiters, significant compressive symptoms, local symptoms refractory to LT₄ therapy, or the inability to rule out malignancy (typically in the setting of nodules or rapid growth).²⁵

Painless or Postpartum Thyroiditis

Sporadic silent (painless) thyroiditis and postpartum thyroiditis are destruction-induced and are probably variants of the same process, distinguished only by the relationship to pregnancy.²⁶ Along with subacute thyroiditis, these conditions are characterized by the onset of thyrotoxicosis and a goiter, and

low 24-hour RAIU. Even excluding postpartum cases, there is a female predominance by 2:1 and the age range of affected patients is broad. The cause appears to be autoimmune, but the genetic predisposition is low. There is no fever or malaise and the goiter is painless but persistent. Thyroid autoantibody titers are often high, and the erythrocyte sedimentation rate (ESR) is usually normal. Thyroid function is dynamic and follows a pattern similar to that of subacute thyroiditis with an abrupt onset of thyrotoxicosis followed by a period of euthyroidism, then hypothyroidism. At the histologic level, lymphocytic infiltration is present along with destruction of follicular cells. If it is pregnancy associated, it is likely to relapse with future pregnancies. If symptoms of thyrotoxicosis are significant, β -adrenergic-blocking drugs may be used, but antithyroid drugs are not appropriate because the gland is not hyperfunctioning at the follicular cell level. If LT_4 therapy is instituted during the hypothyroid phase for symptomatic relief, it can be withdrawn after 6 to 9 months to determine if recovery has occurred.

Subacute Thyroiditis

Subacute thyroiditis is a common form of thyroiditis that affects women more often than men by a 5:1 ratio and often in the age group of 20 to 60 years. There are a number of synonymous terms, such as de Quervain thyroiditis, giant cell thyroiditis, pseudogranulomatous thyroiditis, subacute painful thyroiditis, and subacute granulomatous thyroiditis. The cause is not entirely certain, but it appears to be virally related and a prodrome consistent with an upper respiratory viral infection is very common. The patient often has fever, malaise, and an exquisitely painful and firm goiter that is transient. The goiter is usually unilaterally dominant, and the patient may have pain that radiates to the ipsilateral ear. Giant cells (which may also be observed on FNA) support the diagnosis and granulomas often infiltrate the thyroid. Consistent with follicular cell destruction, serum Tg levels may be elevated. Antithyroid antibodies may be present in low titers and the ESR is often high. A 24-hour RAIU is usually quite low (<5%). Management is similar to painless thyroiditis in that beta blockers may be used, but antithyroid medications are not useful. Salicylates or nonsteroidal anti-inflammatory drugs (NSAIDs) are adequate to control pain in most cases, with the occasional need for oral glucocorticoids. Although the course of disease can be protracted for weeks or months, resolution is common and management is usually limited to management of symptoms.

Amiodarone-Induced Thyrotoxicosis or Thyroiditis

The antiarrhythmic drug amiodarone causes thyroid dysfunction in 15% to 20% of patients. Thyroid dysfunction can include hypothyroidism and amiodarone-induced thyrotoxicosis (AIT) which has two forms: Type I which is often associated with pre-existing multinodular goiter and is the result of the iodine load provided by amiodarone; Type II is more frequent and is the result of destructive thyroiditis. Type I AIT is characterized by a diffuse or nodular goiter with increased vascularity noted on thyroid US and is primarily treated with withdrawal of amiodarone (if feasible) and initiation of methimazole with or without potassium iodide.²⁷ Type II AIT is characterized by a normal thyroid gland without hypervascularity on thyroid US and is treated with withdrawal of amiodarone (if feasible) and corticosteroids, while methimazole is ineffective.²⁷ Medical treatment of AIT is difficult because of both the long half-life of the drug and the effects of thyrotoxicosis on cardiac function in patients already with underlying heart disease. If hyperthyroidism is severe in either type I or II, thyroidectomy may be required to resolve the thyrotoxicosis rapidly and definitively and in some cases to allow for continuation of amiodarone.

Acute Thyroiditis

Acute thyroiditis refers to a rare suppurative condition most commonly caused by the bacterial pathogens *Staphylococcus aureus* and *Streptococcus pyogenes*. A clinical prodrome, usually a viral or bacterial upper respiratory infection, may occur and the patient is often affected by a significant fever and malaise and may have radiating pain to the region of the ipsilateral ear. A painful but ultimately transient goiter may be evident, which is often the result of a thyroidal or perithyroidal abscess. The patient usually remains euthyroid and antithyroid antibody titers are normal. ESR may be elevated. Bacterial infection of the thyroid may occur via hematologic spread from a distant site or local infiltration from other head and neck infections. Recurrent cases of acute thyroiditis may be related to a fistulous communication with the pyriform sinus and is an indication for surgical intervention.

Riedel Thyroiditis

Also known as Riedel struma or invasive fibrous thyroiditis, this rare disorder affects mainly women (by

a ratio of 4:1) and usually occurs between the ages of 30 and 60 years. The cause is unknown and a genetic predisposition is not apparent. The patient presents with a painless but persistent, and often progressive, goiter. Patients are usually euthyroid at presentation but may eventually become hypothyroid. They may have detectable antithyroid antibody titers and a normal ESR. If obtained, the 24-hour RAIU is often normal or somewhat decreased. Physical examination reveals an exceptionally firm goiter often described as “woody.” Most commonly, this is a diffuse, bilobar process. Histologically, the disease is characterized by extensive fibrosis, which may progress to a point of compression of adjacent structures such as the trachea and esophagus. Riedel thyroiditis is often accompanied by other equally mysterious focally sclerotic conditions such as retroperitoneal fibrosis, mediastinal fibrosis, retro-orbital fibrosis, and sclerosing cholangitis.²⁸ Because of its infiltrative nature, it is important to differentiate Riedel thyroiditis from thyroid carcinoma. FNA is often inadequate and core-needle or open biopsy may be required. If substantial compression exists, surgery is often required to relieve these symptoms. Extensive resection is often unsafe or impossible due to infiltration of the thyroid with the surrounding structures, and wedge resections, especially of the isthmus, may be effective in relieving tracheal compressive symptoms. Medical therapy, including corticosteroids, methotrexate, or tamoxifen, may have a positive impact in the chronic setting.²⁹

NODULAR THYROID DISEASE AND GENERAL TREATMENT CONSIDERATIONS

Nontoxic Multinodular Goiter

From a world health perspective, endemic goiter is still a significant issue. Endemic goiters are caused by dietary iodine deficiency, which ultimately is also responsible for congenital hypothyroidism syndrome (historically known as endemic cretinism). Iodine deficiency in a region is addressed over time by iodination of dietary components (e.g., salt, bread flour, or vegetable oil).

In endemic goiter, T_4 levels may be normal or decreased, whereas T_3 levels are normal or often increased. This reflects an adaptive regulatory mechanism by which the thyroid preferentially shifts production to the more biologically potent T_3 . Exogenous thyroxine therapy will induce a decrease in goiter size in roughly 80% of patients treated. Resection may be indicated for large size, increase in size while on T_4 , or compression of the trachea, esophagus, or superior vena cava.

In most developed countries, the term *goiter* generically refers to the group of diseases causing thyroid enlargement in patients not affected by iodine deficiency. In common usage, *goiter* typically refers to patients with nodular goiter. Asymptomatic multinodular goiter is common, and unless there is concern of a malignant nodule, thyroidectomy is not usually indicated. Sometimes, because of the number of nodules of significant size (>1 cm), repeated FNA during longitudinal observation becomes impractical and patients may choose thyroidectomy to simplify management. Compressive symptoms involving the airway or esophagus causing breathing difficulties or dysphagia are an indication for thyroidectomy, as is a multinodular goiter causing subclinical or obvious thyrotoxicosis (toxic multinodular goiter). Total thyroidectomy is the procedure of choice because of the significant chance for recurrent nodular degeneration of the thyroid remnant after subtotal thyroidectomy. If a goiter develops in a substernal position, thyroidectomy is warranted because of the inability to monitor continuing growth in the mediastinum. If tracheal compression develops gradually, it may be largely asymptomatic until a critical point of narrowing is reached, which inhibits passage of air in a relatively sudden and progressive manner. Because all of the important attachments to the thyroid parenchyma remain in the neck, even very large substernal goiters can be removed through a cervical incision and less than 5% will require partial sternotomy.³⁰

Solitary or Dominant Thyroid Nodule

Nodular thyroid disease is clinically appreciated in approximately 4% to 7% in the general population; however, thyroid nodules are in fact present in up to 60% of patients undergoing autopsy. The majority of thyroid nodules are benign with around 5% harboring malignancy. The incidence of thyroid cancer has been increasing with a disproportional increase in small papillary thyroid cancers.³¹ This increase is only partially explained by improved surveillance. Appropriately identifying patients with malignancy that require operation while appropriately avoiding operation for the majority of patients with benign, asymptomatic nodules can be a challenging task ([Algorithm 75-1](#)).

When assessing a patient with a solitary thyroid nodule, the physician should first determine patient risk factors that increase the likelihood of malignant disease. A new thyroid nodule that occurs at the extremes of age is more likely to be malignant than one that occurs in the third through seventh decades. The risk of a solitary thyroid nodule in a child under 18 being malignant is approximately 22%.³² Patient gender itself does not generally confer risk of malignancy, and the fact that thyroid cancer occurs in a greater number of women than men is related somewhat to the increased prevalence of nodular thyroid disease in women.

Many factors apparent on physical examination or imaging can also be used to assess the potential for malignant disease in the patient with a thyroid nodule. The consideration that nodular disease is uninodular (e.g., solitary) instead of multinodular has traditionally implied that the former situation is more concerning for malignancy, however, in the era of thyroid US, this distinction is overemphasized because at least half of nodules considered solitary by clinical examination are ultimately found to be a dominant nodule within a multinodular goiter. The characteristics of a nodule assessed by physical examination (size, firmness, and texture) have a limited ability to predict malignancy, but significant fixation to surrounding tissues can heighten the level of concern for invasive malignancy. Palpable lymphadenopathy or ultrasonographically abnormal-appearing lymph nodes in the central or lateral cervical compartments is certainly concerning for potential malignancy. Although many patients with benign thyroid disease describe hoarseness or a change in voice, this is often largely subjective and is of limited concern unless accompanied by objective hoarseness and ipsilateral RLN paralysis confirmed on laryngoscopic examination. In a patient with a firm thyroid gland in the setting of hypothyroidism, Hashimoto's thyroiditis is a common underlying etiology. Patients with rapidly enlarging, firm thyroid gland with indistinct nodularity should raise concern for thyroid lymphoma or anaplastic thyroid cancer.

A critical question in assessing any patient with a thyroid nodule is whether any history of radiation exposure exists. At least 90% of radiation-associated thyroid cancers are papillary thyroid cancer. Typical exposures to radiation in the 1940s and 1950s included external beam irradiation treatment for acne, tinea capitis, external otitis, recurrent tonsillitis, or neonatal thymic enlargement. In the current era, excessive diagnostic radiation or high-dose therapeutic irradiation (e.g., treatment of lymphoma or head and neck malignancies) can contribute to a relevant exposure. There appears to be a linear relationship between the dose of radiation and the risk for thyroid cancer, with even a higher risk among those exposed at a young age.³³ The typical latent period between exposure and clinically evident cancer appears to be in the 3- to 8-year range. It is not clear when, if ever, the risk is no longer present. Another source of radiation exposure to the thyroid gland is nuclear fallout, related to either atomic weapons or nuclear power plant accidents, such as Chernobyl in 1986. Acute γ -radiation exposure is likely the main risk factor, but longer-term exposure to diverse radioisotopes of iodine that secondarily contaminate the regional water and food supplies may also be contributory.

Algorithm 75-1. Management algorithm for thyroid mass. TFTs, thyroid function tests; US, ultrasound; FNA, fine-needle aspiration; FLUS, follicular lesion of undetermined significance; AUS, atypia of undetermined significance; RAI, radioactive iodine; MNG, multinodular goiter.

Another critical question to investigate is whether a family history of thyroid cancer or associated conditions exists. The key issue is to uncover a family history of medullary thyroid cancer, which suggests the potential for an inherited syndrome such as familial medullary thyroid carcinoma (FMTC) or multiple endocrine neoplasia type 2. Papillary thyroid cancer, however, may have a familial association as well, either independently or, more commonly, associated with Cowden syndrome or Gardner syndrome (familial adenomatous polyposis).

In most situations, extensive thyroid function testing is not necessary and a TSH is all that is required. After initial clinical assessment, thyroid nodular disease is often assessed by US. Relevant factors include the size of the nodule and other sonographic characteristics previously explained. Also important is whether the nodule is truly solitary or whether there are additional nodules, especially in the contralateral lobe, which may affect the specific surgical recommendations with regard to hemithyroidectomy or total thyroidectomy. Symptomatic thyroid cysts may be managed with aspiration alone, ethanol injection treatment or thyroidectomy.³⁴

The utility of thyroid scintigraphy in patients with normal thyroid function tests is very limited and should not be routinely used to evaluate thyroid nodules. The only helpful role for radioiodine scan is with patients with hyperthyroidism to determine if the overproduction of thyroid hormone is due to a single thyroid nodule (toxic adenoma), multiple thyroid nodules (toxic multinodular goiter), or diffuse hyperplasia (Graves disease). In the era of US and FNA, the additional diagnostic information provided by knowing if a nodule is “cold” or “photopenic” is very limited since the indications for FNA lie primarily in the nodule size, the US appearance, and the patient’s risk factors.

Thyroid Fine-Needle Aspiration Biopsy

FNA is the cornerstone of diagnostic evaluation of a thyroid nodule. Cytologic analysis of FNA samples can reliably identify colloid nodules, benign nodular hyperplasia, thyroiditis, papillary thyroid carcinoma (PTC), medullary thyroid carcinoma, and anaplastic thyroid carcinoma. FNA may suggest an extranodal thyroid lymphoma, but usually more tissue (generally in the form of core-needle biopsy, or incisional/excisional biopsy) is required for confirmation of the diagnosis and flow cytometry.

Standard disposable needles ranging in size from 23 to 27 gauge and 3- to 10-mL syringes are used for thyroid or cervical lymph node FNA. After the target nodule is located with US, FNA is performed with US guidance and multiple passes through the most concerning appearing solid portions of the nodule are made. An average of three separate biopsy maneuvers per nodule is reasonable practice. The technique does not rely heavily on aspiration or suction as the name might imply. The ideal sample remains mostly in the needle hub and barrel before expelling it onto a slide or into a fixative for cytologic preparation.

4 There are multiple cytologic classification systems used for thyroid FNA with corresponding recommendations for management. The Bethesda system is one of the more widely used systems which is outlined in [Table 75-1](#).³⁵ A nondiagnostic FNA lacks the minimum of 6 groupings of thyroid cells consisting of at least 10 cells per group. The incidence of nondiagnostic biopsies can be reduced with US guidance and onsite cytopathologic analysis for adequacy of the specimen. The Bethesda system divides the prior *indeterminate* category into category III: atypia of undetermined significance/follicular lesion of undetermined significance and category IV: Follicular neoplasm. There is a recommendation for repeat FNA for category III results rather than diagnostic thyroidectomy as was typical for previously defined indeterminate nodules. The use of molecular marker analysis in indeterminate thyroid FNA specimens is an evolving concept with several tests available which analyze FNA tissue for various genetic mutations (BRAF, RAS, RET/PTC, and others).³⁶ The prognostic utility of molecular testing seems most useful when cytopathology is indeterminate (Bethesda categories III and IV) and has limited added value when cytopathologic analysis is more definitive (Bethesda categories II, V, and VI). Additionally, when other indications for thyroidectomy exist such as local pressure symptoms, multiple large nodules, or patient preference, the role of these gene expression profiling tests may be limited and perhaps needlessly costly.³⁷ FNA classified as follicular lesions or Hürthle cell lesions (Bethesda category IV) may require at least partial thyroidectomy (e.g., lobectomy) to determine whether it is a follicular (or Hürthle cell) adenoma or follicular (or Hürthle cell) carcinoma which can be distinguished only by the demonstration of capsular or vascular invasion on surgical histopathology. FNA should have a false-

positive rate of 0% to 0.5% and a false-negative rate of 0% to 5%.

DIAGNOSIS

Table 75-1 The Bethesda Classification System for Thyroid FNA Cytology

Bethesda Classification	Incidence of All Thyroid FNAs (%)	Cytologic Appearance	Risk of Malignancy (%)	Recommendations for Management
I: Nondiagnostic	5–10	Insufficient follicular cells for analysis	8–10	Repeat FNA
II: Benign	60–70	Hyperplastic follicular cells, colloid nodule, thyroiditis	1–4	Surveillance follow-up
III: Atypia of undetermined significance (AUS) or follicular lesion of undetermined significance (FLUS)	5	Few cells with focal features of nuclear grooves, intranuclear inclusions, atypical lymphoid infiltration	15–45	Repeat FNA with or without molecular testing
IV: Follicular neoplasm or suspicious for follicular neoplasm	5	Scant or absent colloid, microfollicular arrangement, cellular crowding, larger follicular cells	25–50	Hemithyroidectomy if solitary; total thyroidectomy if bilateral
V: Suspicious for malignancy	5	Subtle or focal nuclear and architectural changes seen in PTC, often found to be follicular variant of papillary cancer	70–80	Hemithyroidectomy or total thyroidectomy
VI: Malignant	5	Nuclear grooves, intranuclear inclusions, psammoma bodies	95–99	Total thyroidectomy with or without neck dissection

FNA, fine-needle aspiration; PTC, papillary thyroid carcinoma.

THYROID MALIGNANCY AND GENERAL TREATMENT CONSIDERATIONS

Thyroid cancers exhibit a wide spectrum of behavior, from the inconsequential, occult, well-differentiated thyroid carcinoma to the nearly uniformly fatal undifferentiated anaplastic cancers. Fortunately, at least 98% of thyroid cancers are well-differentiated and long-term prognosis is excellent. There has been an increasing incidence of thyroid cancer primarily due to increasing rates of papillary thyroid cancer with relatively stable rates of other variants.³¹ The general treatment strategy for thyroid carcinomas includes surgical resection, staging of disease, appropriate adjuvant treatments, and secondary screening and follow-up.

Tumor Classification

Thyroid cancers of follicular cell origin are PTC and its variants, follicular thyroid carcinoma and Hürthle cell carcinoma (HCC). Medullary thyroid cancers are derived from parafollicular (C-cells). There is a spectrum of dedifferentiation that can occur in PTC ranging from variants such as tall cell or insular variants. Anaplastic carcinoma represents very dedifferentiated thyroid cancer and carries an aggressive phenotype and poor prognosis. A number of thyroid cancer classification systems exist. The American Thyroid Association (ATA), the Armed Forces Institute of Pathology (AFIP), and the World Health Organization (WHO) all consider papillary thyroid cancers (including classic papillary carcinoma, mixed papillary–follicular variants, follicular variants, and follicular thyroid carcinomas [FTC]) as DTC. Still, some disagreement exists about the classification of HCCs or oxyphilic carcinoma as a subtype of follicular thyroid carcinoma or as its own category. Support for considering HCC as a subtype of follicular thyroid carcinoma includes the histologic demonstration of the transition of follicular to Hürthle cells, an intact TSH receptor adenylate cyclase system in Hürthle cells, and the ability of Hürthle cells to produce thyroglobulin and thus maintain Tg positivity on immunohistochemical staining.³⁸ Other characteristics, however, such as higher oncogene expression in HCC than FTC and the general impression that HCC can display a more aggressive clinical course than FTC cause some to classify HCC tumors outside the FTC family.

Papillary Thyroid Carcinoma

PTC accounts for approximately 85% of thyroid carcinomas. It occurs across a wide spectrum of ages from childhood to the elderly, with peak incidence in the third and fourth decades of life, and is more

common in females than males. PTC is especially prevalent in iodine-sufficient regions of the world while follicular carcinoma has relatively higher incidence in iodine-deficient regions. Papillary carcinoma arises from the follicular cells, is characterized by papillary architecture, calcifications, psammoma bodies, squamous metaplasia, and fibrosis. Cytology is diagnostically important and typical findings include large, overlapping nuclei that are optically clear (Orphan Annie nuclei) and intranuclear grooves. Greater than 30% of PTC is multicentric and found throughout the thyroid. Although multifocality does not signify a worse prognosis, this characteristics may support the rationale for total thyroidectomy. The incidence of cervical lymph node metastases varies across series and is influenced by whether lymphadenectomy is performed for prophylactic or therapeutic reasons. Central neck (level VI) lymphadenectomy performed prophylactically (in the absence of clinically detectable metastasis) demonstrates metastasis in 30% to 80%, however the clinical relevance of micrometastatic disease is debatable. Therapeutic neck dissection for clinically positive lymph node macrometastasis is recommended as the standard of care.¹² Distant metastases occur in 1% to 8% of patients with PTC typically presenting as pulmonary nodules.³⁹ At least 70% of PTC take up radioiodine and RAI scanning and ablation are important parts of the treatment strategy. As a whole, the prognosis for PTC is excellent, especially in those patients with tumors that define a low risk for recurrence.

Variants of Papillary Carcinoma. The follicular variant of PTC essentially combines the histologic and architectural appearance of follicular tumors with the cytologic features of papillary carcinoma. In terms of treatment and biologic behavior, this variant behaves in the same manner as classic PTC. The dilemma caused by this variant is that in contrast to classic PTC it is very difficult to diagnose on frozen section analysis. It is often interpreted as a follicular lesion with the final diagnosis deferred until formal histopathology, to identify the atypical features, is complete. More aggressive variants of papillary carcinoma include tall cell, columnar, and diffuse sclerosing types, which also exist along the spectrum of dedifferentiation. The tall cell variant is associated with more extrathyroidal extension, angiolymphatic invasion and lymph node involvement resulting in higher rates of recurrence.⁴⁰

5 Papillary Microcarcinoma. PTCs less than 1 cm in size are considered microcarcinomas (occult or incidental tumors). They may be multifocal and are usually clinically silent until thyroidectomy is performed for another indication. Although they are by definition malignant, this group of tumors requires a different set of considerations based on their biologic behavior and patient outcome. Prognosis is exceptionally good, with a 0.4% cause-specific mortality rate.⁴¹ A solitary microcarcinoma found after lobectomy is considered adequately treated with lobectomy alone and completion thyroidectomy or radioiodine scanning are not typically indicated. Somewhat in contrast, if these microcarcinomas are diagnosed preoperatively, which may be difficult because of their small size, thyroid resection is usually recommended. Some groups, however, have chosen to follow these patients closely with US and have shown that only 8% significantly increase in size, 3.8% develop new lymph node metastasis and 6.8% progress to clinical disease over 10-year observation period and that patients older than 60 years and those with contraindications to thyroidectomy may be the best candidates for this observational strategy.^{41,42} However, there have also been reports of lymph node metastasis in papillary microcarcinoma and occult primary tumors not identified on histopathology, suggesting that a small subset of microcarcinomas have potential for more aggressive behavior.

Molecular Markers in Thyroid Cancer

6 Molecular testing of thyroid tumors to help characterize thyroid tumors in the pre- and postoperative setting is becoming increasingly useful. Mutations in the MAPK pathway including BRAFV600E, RAS and RET are present in the majority of papillary thyroid cancer while RAS mutations and the PAX8–PPAR γ rearrangement are common in follicular thyroid cancer. In the preoperative assessment of thyroid nodules, molecular testing of FNA samples can identify presence of these mutations and if present may be useful in determining the need for and the extent of thyroidectomy and nodal dissection.⁴³ Mutation of the BRAF gene in papillary carcinomas is estimated to be present in up to 60% of cases and is associated with a more aggressive phenotype and increased recurrence and mortality.⁴⁴

Follicular Carcinoma

FTC accounts for approximately 10% of thyroid cancers. Again, there is a female-to-male predominance, and the incidence begins to increase in the fifth decade of life. Determination that a follicular lesion/neoplasm is a carcinoma is contingent not only on the specific cellular architecture, but also on the findings of vascular and capsular invasion. This determination is rarely able to be made on FNA or

frozen section and often requires final surgical histopathology analysis.⁴⁵ FTC is often more advanced and locally infiltrative of muscles and perithyroidal vascular structures at the time of diagnosis compared with PTC. Because of this difference in stage at diagnosis, the overall 10-year survival for patients with FTC is slightly worse than for those with PTC, but when patients are matched for age and stage with PTC, this difference largely disappears.⁴⁶ In contrast to PTC, follicular cancers are usually solitary. FTC tends to spread hematogenously and approximately one-third of patients have distant metastases of the lung and bone at the time of diagnosis. Lymph node involvement is less common than in PTC and is limited to only about 10% of patients. At least 80% of FTC will take up radioiodine, making this an important consideration in postoperative imaging and adjuvant treatment.

Minimally Invasive Follicular Carcinoma. Follicular neoplasms with demonstrable capsular invasion, but no vascular invasion, are classified as minimally invasive follicular cancers. These patients have an excellent prognosis, conceptually equivalent to patients with incidental papillary microcarcinomas. If such a tumor is found after hemithyroidectomy, completion thyroidectomy and radioiodine therapy are generally not indicated.⁴⁷

Hürthle Cell Carcinoma

Malignant Hürthle cell neoplasms account for less than 5% of thyroid carcinomas, are more prevalent in women than men, affect patients slightly older than those with PTC or FTC and are more often associated with lymph node metastases and distant metastases. Hürthle cells are frequently present on FNA cytology and the possibility of HCC is included in the diagnostic differential for these nodules. Patients with Hashimoto disease or colloid nodules commonly contain Hürthle cells; however, it is the nodule that contains almost entirely Hürthle cells that raises concern for HCC. If HCC is suggested by FNA cytology, a diagnostic thyroid lobectomy is required to definitively establish the nature of the tumor. Hürthle cell cancers can have higher rates of lymph node metastasis and more aggressive nature compared to PTC and FTC therefore many surgeons advocate total thyroidectomy for any Hürthle cell carcinoma. Despite a likely follicular cell origin, only around 10% of HCC tumors take up radioiodine. Surgery therefore is the mainstay of treatment and total thyroidectomy is often combined with central compartment lymphadenectomy and perhaps modified radical neck dissection if lateral compartment lymph node involvement is present.

Anaplastic Carcinoma

Although it formerly accounted for a larger fraction of thyroid malignancies, undifferentiated or anaplastic cancer now accounts for just 1% to 2% of thyroid cancers. Most commonly, it occurs in elderly patients with a long-standing history of a goiter. There is significant evidence to infer that most anaplastic thyroid cancers of the spindle cell or giant cell type arise from transformation of follicular or papillary carcinoma. Anaplastic thyroid carcinoma is one of the most aggressive and rapidly lethal malignancies known. Nearly all are too far advanced at the time of diagnosis to be adequately treated by currently available therapies. The diagnosis may be made by appropriate clinical suspicion (rapidly growing firm thyroid mass) and FNA; however, core-needle or incisional/excisional biopsy may be required. If airway compromise is present or impending, operation may include debulking and tracheostomy. Occasionally, a small anaplastic cancer is found that is confined to the thyroid or is minimally invasive to surrounding tissues. Aggressive resection may be legitimately considered, especially in a young patient. The long-term prognosis for these patients, however, is usually limited by metastatic disease, which may not be apparent at diagnosis. Adjuvant or primary palliative therapy consisting of chemotherapy and external beam radiotherapy is frequently employed. It is common to see a measurable response early in therapy, but eventual tumor progression is typical. Chemotherapeutic regimens often include some combination of taxane (paclitaxel or docetaxel) and/or doxorubicin and/or platin (cisplatin or carboplatin), however, the overall impact is often very limited.⁴⁸ Radiation therapy can be used as primary treatment often in combination with chemotherapy or as adjuvant treatment following surgery with typical total radiation doses of 40 to 60 Gy. Most often, chemotherapy and radiotherapy follow an operation performed for diagnosis or airway protection, but such a regimen may also be used occasionally as neoadjuvant therapy before an attempt at resection is undertaken. A recent trial suggested a trend toward improved survival when combretastatin A-4 (fosbretabulin), a tubulin-binding compound, was added to carboplatin/paclitaxel in the treatment of anaplastic cancer postthyroidectomy.⁴⁹ Median survival for anaplastic thyroid cancer remains low at 5 months with a 20% 1-year survival for all patients.

Staging of Differentiated Thyroid Cancer

A number of patient factors have been investigated to predict risk and prognosis for patients with DTC, such as age, gender, tumor size, involvement of lymph nodes, extrathyroidal invasion, tumor grade or histologic features, and completeness of surgical removal. Although there are differences in these systems, in general, they agree that younger patients with smaller tumors have an excellent prognosis with decreased risk of recurrence and death compared with older patients. One early prognostic staging scheme was the AGES system (age, histologic grade, extrathyroidal disease [invasion and distant metastases], and tumor size).⁵⁰ Although useful, the scheme was later modified to exclude histologic tumor grade because there was no uniform agreement on DTC grading by pathologists. Another system is the AMES system (age, metastases, extrathyroidal invasion, and tumor size), which was originally described for patients with DTC.⁵¹ The main criticism of this scheme is that it was defined based on a patient population that included both papillary and follicular thyroid carcinomas, and that there was no accounting for those patients with low-risk versus high-risk FTC. Another useful prognostic system is the MACIS scoring system (metastases, age, completeness of resection, extrathyroidal invasion and distant metastases, and tumor size). This system calculates a composite score based on these factors, then stratifies prognosis in proportion to these scores (<6.00 is very low risk and >8.00 represents greatly increased risk).⁵² The European Organization for Research on Treatment of Cancer (EORTC) based its prognostic scoring system on a multivariate analysis of patients with all types of thyroid malignancies and found that patients with scores of less than 50 had a 5-year survival rate of 95%, whereas those with scores greater than 109 had a 5-year survival rate of 5%.⁵³ This system has not been universally adopted for use in DTC because the high-risk, poor-prognostic group contained a large fraction of patients with anaplastic thyroid cancer. The familiar TNM system (tumor size, nodal status, and distant metastases) is also used to provide prognostic information for patients. When used for thyroid cancer, the TNM system has been modified to account for the risk-reducing influence of low patient age such that patients <45 years are limited to stage I and II diseases. (Table 75-75). This system can provide consistency when comparing patients across different series. This system, like all prognostic scoring systems, still has limited utility in guiding initial treatment decisions (e.g., extent of resection) because the important components are unable to be determined until after resection. All patients with anaplastic cancer are considered to have stage IV disease which is further subcategorized into IVa (confined to thyroid), IVb (extrathyroidal extension), and IVc (metastatic disease).

STAGING

Table 75-2 Tumor, Node, Metastasis Staging System for Differentiated Thyroid Carcinoma (Papillary and Follicular Types)

Stage	Age <45 yrs	Age >45 yrs
I	Any T, Any N, M0	T1, N0, M0
II	Any T, Any N, M1	T2, N0, M0;
III		T3, N0, M0; or T1–3, N1a, M0
IV		T4, N0, M0; or T4a, N1a, M0; or T1–3, N1b, M0
IVB		T4b, Any N, M0
IVC		Any T, Any N, M1

T1, <2 cm; T2, 2–4 cm, >4 cm; T3, >4 cm; T4a, extrathyroidal extension; T4b, invades prevertebral fascia or encases carotid artery or mediastinal vessels; N0, no nodal involvement; N1, regional nodal metastases; N1a, metastasis to level 6 lymph nodes; N1b, metastasis to unilateral, bilateral, or contralateral cervical or superior mediastinal lymph nodes; M0, no distant metastases; M1, distant metastases.

Medullary Carcinoma

MTC arises from the parafollicular C cells and accounts for about 5% to 7% of all thyroid malignancies. Approximately 75% occur in a sporadic fashion and 20% to 25% are familial due to multiple endocrine neoplasia (MEN) types 2A and 2B or familial medullary thyroid carcinoma (FMTC) syndrome. These are autosomal dominant inherited endocrinopathies related to a group of specific mutations of the RET protooncogene on chromosome 10q11.2 (Table 75-3). The familial forms of MTC have different degrees of aggressiveness: FMTC has the most indolent course, MEN 2B has the most aggressive course, and

MEN 2A is intermediate. Most sporadic MTC is relatively slow growing and may be quite indolent and typically do not present before 30 years of age. However, a subset of patients with sporadic MTC have a much more aggressive course. Approximately 20% of patients thought to have sporadic MTC may in fact be index cases of FMTC. Therefore, any patient with a new diagnosis of MTC should have genetic testing for the RET protooncogene mutations associated with MEN 2 and FMTC. Appropriate screening for pheochromocytoma (which would be treated prior to thyroidectomy) and hyperparathyroidism are required. The variability in biologic behavior in sporadic and FMTC accounts for the overall 10-year survival rate of approximately 50% for all patients combined.

FNA can be diagnostic for medullary cancer, especially if the specimen is stained for calcitonin. MTC is unique in that calcitonin and carcinoembryonic antigen (CEA) are specific tumor markers used for diagnosis and to guide subsequent follow-up. The degree of calcitonin elevation roughly corresponds to extent of disease and levels >400 pg/mL should prompt evaluation for extracervical metastasis with cross-sectional imaging. Overall, MTC is more aggressive than other DTCs and is more likely to metastasize such that 50% to 75% of patients with sporadic MTC have nodal metastases at the time of diagnosis. Nodal metastasis is correlated with tumor size and contralateral cervical metastases are synonymous with systemic disease.⁵⁴ Distant metastases commonly involve the liver, lungs, and bone.

The treatment strategy for MTC is somewhat distinguished from that of PTC or FTC. Due to the high likelihood of lymph node metastases and the fact that radioiodine is not available as an effective adjuvant therapy, a more extensive initial surgical resection is warranted. With few exceptions, the minimum appropriate operation for MTC is a total thyroidectomy with central compartment lymphadenectomy (level VI).⁵⁵ Patients with lymph node involvement in the lateral compartment should undergo total thyroidectomy with central and lateral neck dissection which includes lymph node levels II, III, IV, V and VI. Following initial surgery, an undetectable serum calcitonin is associated with persistent or recurrent disease, while levels which are detectable but <150 pg/mL are often associated with locoregional disease. Experience with remedial neck dissections in an attempt to decrease calcitonin to the normal range or render it undetectable have shown varying results and requires an appropriate search for distant metastases before such an operation is planned.⁵⁶ This may include imaging tests such as CT scanning, US, somatostatin receptor scintigraphy scanning, selective venous sampling for calcitonin levels, and laparoscopy to investigate for hepatic metastases. For most patients, the strategy of observation by clinical examination, biochemical markers (with determination of calcitonin doubling time), and imaging tests is adopted with interval reassessment for resectable regional and metastatic diseases. Resection can be considered for symptomatic lesions and those in a location whereby ongoing growth could cause significant morbidity (e.g., tracheoesophageal groove). Hepatic resections for isolated bulky metastatic deposits can provide palliation. Treatment of clinically significant distant or unresectable disease with targeted agents including vandetanib (an inhibitor of RET kinase, vascular endothelial growth factor receptor [VEGFR], and epidermal growth factor [EGFR]) has shown promise in the context of the general ineffectiveness of traditional cytotoxic chemotherapy.⁵⁷ Somatostatin analogs may also be useful in slowing the growth of the tumor in some patients. External beam radiotherapy may be useful for locoregional tumor control, especially in those patients with evidence of locally aggressive or residual tumor after resection;⁵⁸ however, this should not be employed until appropriate surgical options have been exhausted. The TNM staging system for MTC is outlined in Table75-4.

CLASSIFICATION

Table 75-3 Disease Phenotypes Related to Mutation of the RET Protooncogene

Phenotype	Genetic Defect	Clinical Features	Prevalence (%)
MEN 2A (60%)	Germline mutations in cysteine codons of extracellular and transmembrane domains of RET	Medullary thyroid carcinoma Pheochromocytoma Hyperparathyroidism	100 10–60 5–20
MEN 2B (5%)	Germline activating mutation in tyrosine kinase domain of RET	Medullary thyroid carcinoma Pheochromocytoma Marfanoid habitus Mucosal neuromas (gut) and ganglioneuromatosis	100 50 100 100
FMTC (35%)	Germline mutations in cysteine codons of extracellular or transmembrane domains of RET	Medullary thyroid carcinoma	100

FMTC, familial medullary thyroid carcinoma; MEN, multiple endocrine neoplasia.

7 All patients with MTC (not already known to have familial mutation) should undergo evaluation for germline RET mutations. The best use of genetic testing is to identify the specific mutation in the affected family member, which then guides testing of the progeny. When other kindred members with the mutation are identified, prophylactic thyroidectomy may be performed before malignancy develops with the timing of this guided by the particular codon mutation (Table 75-4).⁵⁵ The thyroid resection must be absolutely complete because the region of thyroid remnant after a near-total or subtotal thyroidectomy is the region that is most densely populated with C cells. The association of primary hyperparathyroidism and MEN 2A should be considered during preoperative planning and enlarged parathyroid glands encountered at the time of thyroidectomy should be removed. A subtotal parathyroidectomy or total parathyroidectomy and autotransplantation (similar to that which would be considered for MEN 1) are excessive options for the parathyroid disease encountered in MEN 2A and, instead, resection may be guided by morphologic changes in the parathyroid glands and intraoperative parathyroid hormone monitoring. Children identified to have MEN 2B should undergo thyroidectomy and central compartment lymph node dissection as soon as the diagnosis is made, definitely by 2 years of age, but even by 6 months of age as guided by mutation analysis (Table 75-5).⁵⁹ If MTC is already evident at the time of RET mutation diagnosis (as opposed to only C-cell hyperplasia), patients should also undergo ipsilateral neck dissection.

STAGING

Table 75-4 Tumor, Node, Metastasis Staging System for Medullary Thyroid Carcinoma

Stage	TNM
I	T1, N0, M0
II	T2, N0, M0 T3, N0, M0
III	T1–3, N1a, M0
IVA	T4a, Any N, M0; T1–3, N1b, M0
IVB	T4b, Any N, M0
IVC	Any T, Any N, M1

T1 <2 cm; T2, 2–4 cm; T3, >4 cm or minimal extrathyroidal extension; T4a, invades larynx, trachea, esophagus or nerve; T4b, invades spine or carotid; N0, no nodal metastasis; N1a, central neck (level VI) metastasis; N1b, lateral neck or superior mediastinal metastasis (levels II,–V, VI); M0, no distant metastasis; M1, distant metastasis.

Thyroid Lymphoma

8 Primary thyroid lymphomas are rare tumors that account for fewer than 5% of thyroid malignancies. The majority are classified as non-Hodgkin lymphomas of B-cell origin. Nearly all arise from within a background of Hashimoto thyroiditis. Most patients present with a rapidly enlarging thyroid mass and compressive symptoms (e.g., dyspnea, dysphagia, choking, and pain) and have a history of hypothyroidism. Modern immunophenotypic analysis often allows for diagnosis with a small amount of tissue obtained by FNA or core-needle sampling. Surgery is typically utilized only to establish the diagnosis with open biopsy if needle biopsy is insufficient. Definitive treatment of thyroid lymphoma includes chemotherapy and radiation. Patients with diffuse large B-cell lymphoma are generally treated with combination chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisone [CHOP] with rituximab) followed by radiation therapy for stage IE or IIE disease.⁶⁰ In those with pure marginal zone B-cell lymphoma (MALT), some have advocated for single-modality therapy (chemotherapy or radiation) given its more indolent behavior, but this still remains controversial and would be limited to those with localized disease.⁶¹

TREATMENT

Table 75-5 Age of Prophylactic Thyroidectomy Based on Genotype/Phenotype Correlation in Medullary Thyroid Carcinoma

Risk Classification	Codon Mutation	Management Recommendation
Level A – Lowest risk	533, 649, 666, 768, 790, 791, 804, 891, 912	Total thyroidectomy ± CCLND before age of 10 yrs or before based on criteria ^a
Level B – Moderate risk	609, 611, 618, 620, 630	Total thyroidectomy ± CCLND before age of 5 yrs or delayed based on criteria ^a
Level C – High risk	634	Total thyroidectomy ± CCLND before age 5 yrs
Level D – Highest risk	883, 918	Total thyroidectomy ± CCLND within first year of life

^aA normal annual basal calcitonin, normal annual neck US, less aggressive MTC family history. CCLND, central compartment lymph node dissection.

Metastases to the Thyroid Gland

Isolated metastases from other primary cancers can occur in the thyroid gland, although they are rare. The most common tumor type to do so is renal cell carcinoma, although it can occur from breast, lung, and gastrointestinal carcinomas, as well as melanoma and sarcoma.⁶² Thyroidectomy can be useful for control of compressive symptoms.

Preoperative Ultrasound

Cervical US plays an important role for preoperative planning prior to thyroidectomy for benign disease and for thyroid cancer. US, which can be performed by the operating surgeon, provides important information including determination of the size and extent of thyroid nodules which may not be palpable on physical examination. Failure to visualize the caudal extent of the lower thyroid lobes in large goiters indicates possible substernal extension which can be further delineated with CT. Preoperative US can also evaluate the cervical lymph nodes in cases of thyroid cancer and particular attention should be paid to evidence concerning imaging appearances (lack of a hilar line, microcalcifications, and loss of the typical flattened ovoid shape) which may not be noted on physical examination alone. Detection by US of nonpalpable lymph node metastases occurs in 24% to 39% of patients with papillary thyroid cancer diagnosed by FNA.^{12,63–65} Even in patients with palpable lymphadenopathy, US can alter the extent of lymphadenectomy in approximately 40% of patients undergoing initial or reoperative surgery.^{65–67}

Extent of Thyroidectomy

9 Thyroidectomy is a primary treatment for DTC and is well accepted to be both effective and safe; however, some controversy persists about the extent of thyroidectomy necessary for low-risk patients. It is generally agreed that surgical options (not typically equivalent) include hemithyroidectomy with or without isthmusectomy for small (<1 cm) low-risk tumors confined to a single focus in the thyroid or total or near-total thyroidectomy for all DTCs. Subtotal thyroidectomy is not an appropriate operation for thyroid cancer. The advantages of total thyroidectomy for all DTCs of follicular cell origin include (a) removal of multifocal intrathyroidal tumors; (b) use of radioiodine to localize and treat small amounts of residual normal thyroid tissue, and more importantly, regional or distant metastases; and (c) the ability to use serum thyroglobulin as a sensitive marker of persistent or recurrent disease. If only thyroid lobectomy is performed, radioiodine treatment is usually not optimal because of the increased avidity for RAI to the normal remaining thyroid lobe compared to thyroid cancer tissue, and thyroglobulin measurements also lose their utility. It has been difficult to demonstrate a survival advantage related to extent of thyroidectomy. However, a study comparing extent of thyroid surgery in patients with PTC showed that patients with PTC greater than 1 cm who underwent total thyroidectomy had a significantly lower risk of recurrence and lower mortality compared with those undergoing thyroid lobectomy.⁶⁸

Lymphadenectomy

10 Therapeutic lymphadenectomy is a well-established treatment of the clinically involved cervical lymph nodes. In general, regional lymph node metastases are found in 30% to 40% of patients, although wider ranges have been reported (20% to 90%).^{63–65} A compartment-oriented approach to lymphadenectomy is currently preferred over the previously advocated technique of selective neck dissection or “berry picking” (removing only grossly positive nodes) if this can be performed without significantly increasing morbidity or mortality. Prophylactic central lymph node dissection (CLND) is a

more controversial component of treatment for papillary thyroid cancer. Central compartment lymph node involvement is both common (can be found in up to 80% of patients with clinically negative nodes) and difficult to treat with a remedial operation in the future.¹² If prophylactic CLND is to be added to the routine performance of total thyroidectomy to treat PTC, it must be assured that the incidence of RLN injury and hypoparathyroidism is not increased. Routine prophylactic CLND can be considered for patients with papillary thyroid cancer and Hürthle cell cancer if it can be done without increasing morbidity.¹² Knowledge of the central neck lymph node status improves staging accuracy in patients over 45 years of age and may influence the use of adjuvant radioiodine treatment.⁶⁹ Residual subclinical disease, as indicated by postoperative serum thyroglobulin levels, may also be decreased using this strategy.⁷⁰ Whether prophylactic central neck dissection will have any benefit to long-term survival will be very difficult to determine given the already excellent prognosis for patients with DTC.

Radioiodine Therapy

Radioiodine may serve diagnostic and therapeutic purposes in the management of follicular-derived thyroid cancer. Low doses are used to demonstrate remaining thyroid tissue or metastatic disease as part of a diagnostic radioiodine scan, whereas higher doses are used for thyroid remnant ablation and for treatment of residual and/or recurrent disease. The timing of the initial postoperative scan is dictated by the physiology of T_4 and the fact that remnant thyroid tissue or DTC must be stimulated by elevated levels of TSH to take up RAI. Although no precise threshold has been established, a general consensus is held that the TSH at the time of RAI should be ≥ 30 mIU/mL to provide adequate stimulation for radioiodine uptake. Traditionally this has been achieved by withdrawal of supplemental thyroxine. The half-life of thyroxine is approximately 7 days, so TSH values are significantly elevated 4 to 5 weeks after total thyroidectomy or withdrawal from thyroxine treatment. To minimize the duration of hypothyroid symptoms, patients can be managed with T_3 (liothyronine) up to 2 weeks prior to scanning, as T_3 has a much shorter half-life (8 to 12 hours) than T_4 . An alternative to thyroid hormone withdrawal is the use of recombinant human TSH (rhTSH) for ^{131}I uptake scans and treatment.⁷¹ The use of rhTSH avoids the long deprivation of thyroid hormone replacement and development of hypothyroid symptoms. rhTSH can also be used to obtain stimulated serum thyroglobulin levels and ^{131}I whole-body scans during thyroid cancer surveillance.

Radioiodine therapy has a dual intended effect of treatment of residual thyroid cancer as well as ablation of any thyroid remnant tissue. The utility of radioiodine ablation of the thyroid remnant in the absence of evidence of residual thyroid cancer is debated. Radioiodine therapy is a rational adjuvant therapy for DTC because most tumor cells retain the ability to concentrate radioiodine. Several studies have shown a decreased rate of recurrence and increased disease-specific and overall survival when ^{131}I treatment is used in patients with stage III and IV diseases and with more aggressive pathologic subtypes.^{72,73} Although there have been no prospective randomized trials with postoperative radioiodine, treatment is recommended for all patients with distant metastasis, primary tumors larger than 4 cm or with gross extrathyroidal extension and those with lymph node metastasis.¹² Radioiodine treatment is generally not recommended for tumors less than 1 cm (unifocal or multifocal) confined to the thyroid, in cases of undifferentiated thyroid cancer or in recurrent tumors that have lost the ability to concentrate iodine. Unfortunately as many as 30% of advanced and recurrent DTC will eventually dedifferentiate, and a portion of these cancers will lose the ability to concentrate radioiodine due to loss of the Na^+/I^- symporter function. Clinical trials are ongoing using a variety of MAPK kinase inhibitors to reverse iodine resistance and therefore make repeat radioiodine treatment a viable option.⁷⁴

External Beam Radiotherapy

External beam radiation is rarely indicated in the treatment of thyroid cancer. Invasive variants which result in gross residual disease after surgical resection may benefit from external beam radiation to assist with local control. This is most often a consideration with tumors that invade the tracheoesophageal axis. This occurrence is frequent with poorly differentiated tumors, but it certainly can complicate advanced DTC as well. It has also been considered for patients with extensive lymph node involvement that is characterized by extranodal extension. Bone metastases are rarely treated completely with ^{131}I and, thus, external beam radiotherapy may be effective often in conjunction with zoledronic acid.⁷⁵ Complications of external beam radiation include skin erythema and desquamation and tracheoesophageal mucositis and its use should be limited to cases where additional operative attempts are unlikely.

Thyroid-Stimulating Hormone Suppression

Levothyroxine therapy to suppress TSH levels below 0.1 mU/L is commonly recommended for patients with high-risk differentiated thyroid carcinoma and between 0.1 and 0.5 mU/L for low-risk patients.¹² TSH is considered a trophic factor for these cancers, however, the efficacy of suppressive therapy is inferred from uncontrolled retrospective studies. It is important to individualize the degree of suppression in patients, balancing the risk of recurrence with the risks of subclinical hyperthyroidism (e.g., osteoporosis, cardiac arrhythmias). If a patient has no evidence of recurrence and has extremely low or undetectable thyroglobulin levels 5 to 10 years after treatment, it may be appropriate to lessen the degree of TSH suppression.

Metastatic Thyroid Cancer

In addition to radioactive iodine therapy there are multiple ongoing clinical trials of tyrosine kinase inhibitors (sorafenib, vandetanib, sunitinib, and pazopanib) in the treatment of advanced or progressive metastatic thyroid cancer with sorafenib recently obtaining FDA approval.⁷⁶ These novel drugs act to partially inhibit multiple tyrosine kinases including BRAF, MEK, and phosphatidylinositol 3-kinase (PI3K), RET and VEGFR and are often used as first-line treatment of metastatic thyroid cancer nonresponsive to radioiodine therapy prior to treatment with cytotoxic agents.

THYROID SURGERY

Thyroidectomy is a safe and effective operation for thyroid disease in the hands of an experienced surgeon. Substantial improvements in anesthesia, antisepsis, and improved hemostasis along with the substantial technical contributions of Albert Theodor Billroth, Theodor Kocher, and William Halsted, among others have provided the basis of modern thyroid surgery.

Technique

There is little, if any, place for subtotal lobar resections (e.g., nodulectomy) and only an occasional role for isthmusectomy alone. Thyroid lobectomy (hemithyroidectomy) is the total extracapsular removal of the lobe and the isthmus while preserving the parathyroid glands, the RLN, and the EBSLN. Total thyroidectomy is merely a matter of performing a thyroid lobectomy on the contralateral side during the same operation. Subtotal thyroidectomy is intentional subtotal lobar resection, either unilaterally or bilaterally, and is rarely indicated except in cases where postoperative thyroid hormone replacement is problematic. Near-total thyroidectomy involves intentionally leaving a minor amount of thyroid tissue to protect the insertion of the RLN and the superior parathyroid gland. When properly performed, near-total thyroidectomy is essentially interchangeable with total thyroidectomy when considering surgical outcomes but still requires post-operative thyroid hormone replacement.

For most thyroid procedures, the patient is placed in a supine position or a semi-Fowler position with the arms tucked to the side. A support is placed transversely under the shoulders to aid in extending the neck. This extension must not be too extreme or postoperative pain may occur in the occipitocervical region.

Thyroid resection should be performed in a logical orderly sequence as follows. After skin preparation, a curvilinear incision is made approximately one to two fingerbreadths above the clavicular heads and not any higher than the level of the cricoid cartilage, disguised in an existing skin crease when possible (Fig. 75-8). Subplatysmal skin flaps are raised to the level of the thyroid cartilage above, the sternal notch below, and laterally to the sternocleidomastoid muscles. The midline raphe is opened to expose the anterior trachea and the thyroid isthmus. The sternohyoid and sternothyroid are then separated from the underlying thyroid lobe, and the perithyroidal and paraesophageal spaces are entered. The middle thyroid veins, which can be identified as they course medial to lateral, anterior to the carotid artery are divided and ligated. If a pyramidal lobe is present, it is mobilized and divided from the fibrous tissue in any remaining thyroglossal duct tract. The anterior suspensory ligament is divided to mobilize the superior aspect of the isthmus.

Dissection of the superior pole of the thyroid must take place in the plane directly adjacent to the thyroid capsule after the largely avascular space between the pole and the cricothyroideus muscle is dissected. To do so more proximally along the superior pole vessels imperils the EBSLN. This nerve is not always visually identified during thyroidectomy, but it can nearly always be preserved by utilizing this technique and observing the anatomy carefully. The EBSLN can often be demonstrated with the

help of a stimulator used in a nerve-integrity monitoring system (see below). Capsular dissection then continues at the inferior pole of the thyroid lobe with preservation of the inferior parathyroid gland followed by capsular dissection of the posterolateral aspect of the thyroid gland with preservation of the superior parathyroid gland and the RLN. [Figure 75-9](#) indicates the plane of dissection relevant to these steps.

Figure 75-8. With the patient's neck extended, the line above indicates the appropriate site of incision for thyroid resection. Camouflage within an existing skin crease is often possible.

Figure 75-9. The capsular dissection necessary to preserve well-vascularized parathyroid tissue and a fully functional recurrent laryngeal nerve begins in the area outlined above.

Unequivocal identification of the RLN should occur early in the operation and involves visual identification of the nerve as it emerges from the mediastinum. Palpation can aid in the process of identification of the RLN as a slightly firm linear structure in the tracheoesophageal groove with the lobe retracted anteromedially. Although helpful in guiding early dissection, this technique cannot supplant visual confirmation. The RLN typically courses posterior to the thyroid. Progressive exposure of the entire surface of the nerve until it inserts into the cricothyroid muscle will allow for identification and preservation of nerve branches. The genu of the RLN occurs near the ligament of Berry and constant visualization of the nerve along with gentle dissection and careful division of the ligament is important to avoid injury.

The ability to routinely preserve well-vascularized parathyroid tissue during thyroidectomy is mandatory for surgeons performing these operations. Normal parathyroid tissue is subtle and may be difficult to identify. It can be distinguished from surrounding fat by a slight brownish color (similar to the color of peanut butter) and a fine capillary vascular pattern that is not present in the adjacent fat or thymus. If a parathyroid is inadvertently removed or is devascularized it should be morcelized and then reimplanted into an easily accessible and viable muscle such as the sternocleidomastoid or strap muscle.

Figure 75-10. Boundaries showing high-risk area of central compartment dissection involving the vascular supply to the superior and inferior parathyroid glands and the recurrent laryngeal nerve.

Figure 75-11. The recurrent laryngeal nerve is carefully isolated and dissected free from surrounding tissue in level VI.

The central compartment level VI lymph nodes are bordered by the hyoid bone cranially, the level of innominate artery caudally, the common carotid arteries laterally, and the prevertebral fascia posteriorly.⁷ Removal of these lymph nodes is an important component of an operation to treat clinically evident lymph node metastasis in thyroid carcinoma and may have an important role to offer in a prophylactic manner to improve nodal staging with its downstream effects on adjuvant radioiodine treatment.⁶⁹ To perform a CLND, the prelaryngeal (Delphian) lymph node(s) adjacent to the pyramidal lobe is excised. After the ipsilateral thyroid lobe is completely resected, the lateral and medial extent of dissection is defined to mobilize the level VI nodes. The superior parathyroid gland must be carefully preserved on its vascular supply as the inferior parathyroid gland is often embedded in the nodal tissue to be removed and often requires autotransplantation (Fig. 75-10). The cervical portion of the RLN is exposed in a retrograde direction toward the mediastinum using gentle dissection to divide the overlying fibrofatty and nodal tissue (Fig. 75-11). Especially on the side ipsilateral to the primary tumor, it is important to remove the nodes located posterior to the RLN and anterior to the prevertebral fascia in addition to the more easily removed nodes located anterior to the RLN (Fig. 75-12). If the nerve is adequately mobilized, this can usually be accomplished en bloc and the nodes may even be left attached to the inferior pole of the thyroid. The block of nodal tissue is then removed down to the level VII superior mediastinal nodes at the superior margin of the innominate vein. In order to accomplish this, the cervical thymus can either be removed or preserved. If the inferior parathyroid is unable to be preserved on its vascular pedicle, it is autotransplanted into the adjacent muscle after confirmation with frozen section that it is indeed parathyroid tissue and not a metastatic lymph node (Fig. 75-13).

Figure 75-12. The recurrent laryngeal nerve is carefully repositioned laterally and medially as needed to dissect all fibrofatty and lymphatic tissue from level VI structures.

Figure 75-13. It is not uncommon for the inferior parathyroid gland(s) to become devascularized during dissection of the central compartment. Devascularized parathyroid tissue should be retrieved, minced into 1-mm pieces, and autotransplanted to the ipsilateral sternocleidomastoid muscle.

Advanced surgical energy instruments for bipolar vessel sealing and ultrasonic scalpels have now been integrated into thyroid resections. The main benefit in thyroidectomy is decreased operative time.⁷⁷⁻⁷⁹ Most series indicate that complication rates (hematoma, RLN injury, and hypoparathyroidism) are comparable to conventional techniques. Heat generation and lateral thermal spread for a particular instrument are critical to understand and may limit safe application near the RLN and parathyroid glands.

Intraoperative monitoring of the RLN and EBSLN function is used to varying degrees with several commercially available nerve monitoring systems. Nerve monitoring requires measurement of vocal cord movement or muscle action potentials with either electrodes on the endotracheal tube or needle electrodes surgically implanted in the cricothyroid muscle. Electric stimulation of the functionally intact RLN produces adduction of the true vocal fold and a measured evoked potential signal. Similarly, stimulation of the EBSLN produces muscular twitch of the cricothyroid muscle. Intraoperative nerve monitoring can clearly aid in identification of the RLN and EBSLN, especially in reoperative procedures; however, there have been no studies demonstrating a statistically significant decrease in nerve injury rates with nerve monitoring.⁸⁰⁻⁸² Therefore, whether or not RLN monitoring is employed, prevention of injury still requires meticulous and precise surgical technique.

Modifications to the traditional transcervical approach to thyroidectomy have been developed at several centers with the goal of decreasing the size of the cervical incision or avoiding a cervical incision altogether. Although the modified transcervical approaches can be minimally invasive with smaller incisions, less dissection and possibly less postoperative pain, the remote access approaches (transaxillary, transareolar, and “facelift”) are not necessarily minimally invasive and often require more extensive dissection to gain access to the thyroid and should be considered purely cosmetic in their benefits.

COMPLICATIONS

Table 75-6 Complications of Total Thyroidectomy

Complications	Incidence (%)
Bleeding	1
Wound infection	1
Thoracic duct leak	1
Hypoparathyroidism	
Transient	9–35
Permanent	0–4
Recurrent laryngeal nerve injury	
Initial operation	
Transient	1–10
Permanent	0–1.4
Reoperation	
Transient	0–22
Permanent	0–13
External branch of superior laryngeal nerve injury	5–28

Complications

The risk of death or major disability during thyroidectomy should be diminutive. The key outcomes by which to measure the quality of surgical care include RLN paralysis and hypoparathyroidism (Table 75-6). Although both complications can occur in a temporary fashion, the persistence or permanence (defined at 6 months after operation) of these complications is a critical measure. For most surgeons, the rate of unintended permanent RLN dysfunction should be no greater than 1% and the rate of permanent hypoparathyroidism should be no greater than 1% to 2%.

Injury to an RLN results in temporary or permanent paralysis of the vocal cord it innervates depending on the degree of injury and presence or absence of repair. At times the main RLN will bifurcate exterior to its insertion into the cricothyroid muscle. In these scenarios the anterior branch typically contains motor fibers and the posterior branch typically contains sensory fibers. Injury to these branches can result in hoarseness and aspiration respectively or in combination if the main RLN is injured. Depending on the specific branch or combination of branches injured, the cord may remain in a paramedian position (also called cadaveric position) or may remain abducted. If the contralateral cord is able to adduct to the midline or beyond, the patient may have a voice that is not particularly hoarse, but is weak. If the cord is paralyzed in the abducted position, vocal quality is very poor because of the difficulty in approximating the cords during speaking. The patient's cough also has a bovine quality where there is a lack of a sharp, percussive initiation. If both vocal cords are paralyzed, consideration of the specific cord positions is even more critical. If both cords are paralyzed in the abducted position, the patient may have a critically limited ability to phonate. In this situation, the patient may gradually develop some degree of airway obstruction as the cords gradually migrate toward the midline. If both cords are paralyzed in the paramedian position, the airway is critically narrowed. In this situation, stridor is usually apparent very soon after extubation and an emergent procedure (e.g., cricothyroidotomy or tracheostomy) may be required to reestablish a patent airway. Intraoperative recognition of RLN injury can be aided with intraoperative nerve monitoring. The particular site of injury can often be identified by progressive distal stimulation of the visualized RLN until loss of signal occurs. If a nerve transection is noted, intraoperative neural repair can be performed with variable regain of function.

Because of greater anatomic variations, the EBSLN is at higher risk for injury than the RLN during thyroidectomy.⁸⁰ The symptoms of injury to the EBSLN are usually less noticeable and may be only slightly evident to the patient, but can be important in the case of the vocal professional. Symptoms of EBSLN injury typically include early vocal fatigue, decreased pitch range, and decreased projection ability. Findings on laryngoscopy are subtle and include bowing and inferior displacement of the affected vocal cord and rotation of the posterior glottis toward the injured side. Laryngeal videostroboscopy or percutaneous electromyography of the cricothyroideus muscle may be required to detect injury in subtle cases. Because there is no effective treatment for this condition, prevention is extremely important.

Examination of vocal cord appearance and function can be performed with indirect or flexible fiberoptic laryngoscopy in a routine or patient selective manner.⁸³ Laryngoscopy is particularly useful in patients with persistent hoarseness or change in voice quality, those with history of prior surgery in

which the recurrent laryngeal or vagus nerves were at risk of injury, those with locally advanced cancer and those with distorted anatomy due to large and/or substernal goiters.

The parathyroid glands are at risk during thyroid resection by virtue of their location which can be firmly invested within the thyroid sheath or occasionally even within the thyroid capsule. Inferior parathyroid glands are ultimately supplied by the ITA. Superior parathyroid glands are often served by the ITA but may also have contributions from the superior thyroid artery. Ligation of the trunk of the ITA proximal to the pedicle to the parathyroid glands must be avoided. Every attempt should be made to mobilize the parathyroid glands away from the thyroid tissue while preserving the blood supply. If the gland appears pale or dark and devascularized, the arterial supply is probably compromised. Such a parathyroid gland is unlikely to survive after the operation and should be autotransplanted. This may be done by mincing the gland into 1-mm pieces and inserting or injecting the pieces into well-vascularized skeletal muscle (e.g., sternocleidomastoid, strap muscle, or pectoralis).⁸⁴ With total thyroidectomy, careful dissection is even more critical than with hemithyroidectomy. Temporary hypoparathyroidism is relatively common and occurs in 20% to 40% of patients after total thyroidectomy and is due to mild devascularization or venous congestion of parathyroid glands during mobilization. Symptoms of hypocalcemia include paresthesias and numbness of the hands, feet, and lips which can be treated with oral calcium with or without vitamin D supplements (e.g., calcitriol). Severe symptomatic hypocalcemia can be treated with intravenous calcium gluconate. Temporary hypoparathyroidism complicating thyroidectomy usually resolves over days to weeks, although occasionally it may take months to do so. Hypoparathyroidism that persists longer than 6 months is usually destined to be permanent. The transient hypocalcemia after total thyroidectomy may be worse in the patient with Graves disease because of the increased bone turnover observed with hyperthyroidism; however, recovery is expected and the incidence of permanent hypoparathyroidism should be no higher than in euthyroid patients.

Regardless of the specific extent or technique of thyroidectomy, these complications can largely be avoided or ameliorated by delicate and deliberate surgical technique. A thorough understanding of the function and anatomy, both normal and abnormal, of the thyroid gland, and of the rationale behind various treatment options, is critical to ensure the best outcomes for our patients.

DISCLOSURES

The authors have nothing to disclose.

Chapter 76

Parathyroid Glands

Gerard M. Doherty

Key Points

- 1 The normal parathyroid glands are flat, ovoid, and red-brown to yellow. Their dimensions are 5 to 7 mm × 3 to 4 mm × 0.5 to 2 mm, and they weigh between 30 and 50 mg each.
 - 2 Parathyroid hormone (PTH) is the single most important hormonal regulator of calcium and phosphate metabolism in humans with direct effects on the skeleton and kidney and indirect effects on the intestine, mediated through vitamin D.
 - 3 The demonstration of an elevated plasma PTH concentration alone does not establish the diagnosis of hyperparathyroidism; with a simultaneous elevated serum calcium level, this finding is virtually diagnostic.
 - 4 A large proportion of patients with the diagnosis of hyperparathyroidism are minimally or asymptomatic and the appropriate treatment for these patients remains controversial.
 - 5 It is routinely possible to identify abnormal parathyroid glands prior to operation for most patients, allowing the surgeon to know where to start the exploration; intraoperative PTH measurement can be used to confirm removal of all hyperfunctioning parathyroid tissue, that is, when to stop the operation.
-

ANATOMY

1 Typically, each person has four parathyroid glands – two superior and two inferior ([Fig. 76-1](#)).¹ The normal parathyroid glands are flat, ovoid, and red-brown to yellow. They measure 5 to 7 mm × 3 to 4 mm × 0.5 to 2 mm and weigh between 30 and 50 mg each. The lower glands are usually larger than the upper glands. The superior glands are most often embedded in the fat on the upper posterior surface of the thyroid lobe near the site where the recurrent laryngeal nerve enters the larynx. The inferior glands are usually more ventral and lie close to or within the portion of the thymus gland that extends from the inferior pole of the thyroid gland into the chest. Although this anatomy is fairly consistent, substantial variations from the usual can occur, and it is essential that the surgeon have a thorough understanding of these anatomic variations.

Variations in parathyroid gland anatomy are primarily caused by differences in patterns of embryogenesis. During the fourth and fifth weeks of fetal development, a series of four pharyngeal pouches develop ([Fig. 76-2](#)). The superior parathyroid gland arises from the fourth pharyngeal pouch in conjunction with the lateral thyroid, and the inferior gland arises from the third pouch along with the thymus. The derivatives of each pouch then migrate together so that the superior parathyroid gland usually remains in close association with the upper pole of the thyroid, although it may occasionally be loosely attached by a long vascular pedicle, migrating caudad along the esophagus into the posterior mediastinum. Occasionally, a gland may be totally embedded in the thyroid parenchyma. The inferior parathyroid gland descends with the thymus, but this migration is extremely variable. Inferior glands can be found anywhere from the pharynx to the mediastinum. Regardless of their location, they usually adhere to the thymus or are within the thyrothymic ligament. Supernumerary glands can be identified in up to 15% of patients, most often in association with the thymus. Autopsy studies suggest that four parathyroid glands are virtually always present.

The arterial supply to both the superior and inferior parathyroid glands is usually from the inferior thyroid artery, although it may arise from the superior thyroid or thyroidea ima arteries or from the rich anastomosis of vessels supplying the larynx, trachea, and esophagus. A mediastinal parathyroid gland that descended during embryonic development usually receives its blood supply from either the internal mammary artery or small arteries within the thymus; however, an enlarged parathyroid gland that grows into the mediastinum usually carries with it the corresponding branch of the inferior thyroid

artery. The inferior, middle, and superior thyroid veins, which drain the parathyroid glands, empty into the internal jugular vein or the innominate vein.

Histologically, the normal adult parathyroid gland is about half parenchyma and half stroma, including fat cells ([Fig. 76-3](#)). In children, the gland is almost entirely composed of parenchymal chief cells. Beginning at puberty, adipocytes appear and, with age, occupy an increasing proportion of the gland. Also with increasing age, acidophilic, mitochondria-rich oxyphil cells are present in increasing numbers and are intermixed with the glycogen-laden, polygonal, water-clear cells. The functional significance of the various cell types remains unclear, although the water-clear cells and oxyphil cells are probably derived from the chief cells and secrete parathyroid hormone (PTH).

PHYSIOLOGY

The primary physiologic role of the parathyroid gland is the endocrine regulation of calcium and phosphate metabolism. Average daily exchanges of these ions from the gastrointestinal tract, bone, and kidney are shown in [Figure 76-4](#).

Calcium

Calcium ion plays a critical role in all biologic systems. It participates in enzymatic reactions and is a mediator in hormone metabolism. Calcium is intimately involved in the physiology of neurotransmission, muscle contraction, and blood coagulation. It is the major cation in bone and teeth. It represents about 2% of the average body weight, and almost all calcium is contained in the skeleton. The normal range of serum calcium is 9 to 10.5 mg/dL (4.5 to 5.2 mEq/L), and the daily variation in a normal person is generally less than 10%. About half of the total serum calcium is in an ionized, biologically active form; 40% is bound to serum protein, mainly albumin, and 10% forms compounds with organic ions, such as citrate. The total serum calcium concentration is a function of the serum protein content, and because hydrogen ion competes with calcium for the same binding sites on albumin, the body fluid pH is important. In general, for every change of 1 g/dL in the serum albumin level, a direct alteration of 0.8 mg/dL occurs in the serum calcium concentration. Almost all the physiologically important activity of calcium is represented by the unbound, or free, fraction.

Figure 76-1. Schematic illustration of the location of the superior (A) and inferior (B) parathyroid glands from 503 autopsy studies. The more common locations are indicated by the shaded areas. The numbers represent the percentage of glands found at each location. Typically, the glands were posterolateral to the thyroid and above or below the junction of the inferior thyroid artery with the recurrent laryngeal nerve.

Calcium is absorbed in its inorganic form from the duodenum and proximal jejunum. The rate of absorption is precisely regulated according to body calcium status. The calcium in the extracellular fluid is constantly being exchanged with that in the intracellular fluid, the exchangeable bone, and the glomerular filtrate. Calcium reabsorption by the kidney is closely related to that of sodium, and about 99% of the filtered load is reabsorbed under normal conditions.

Figure 76-2. A: Pharyngeal arches in a 5-week embryo. The corresponding pouches extend from within the pharynx into each arch. B: Schematic representation of the differentiating epithelium of the respective pharyngeal pouches.

Figure 76-3. A normal adult parathyroid is composed of about half parenchyma and half fat ($\times 150$).

Phosphate

Phosphate anion is also an integral component of most biologic systems. It is critical to the pathways of glycolysis and is the functional group for a number of high-energy transfer compounds, including adenosine triphosphate. It is also the major anion in crystalline bone. Normal levels of plasma phosphate range from 2.5 to 4.3 mg/dL, and the level varies inversely with the serum level of calcium. The relation is such that the product of plasma calcium and phosphate is relatively constant ranging between 30 and 40 (with calcium and phosphate both expressed in mg/dL). When the product is above

this level, the potential for the precipitation of calcium phosphate in body tissues increases.

In contrast to the percentage of calcium absorbed, the percentage of phosphate absorbed from the diet is relatively constant, and excretion usually provides the major mechanisms for regulating phosphate balance (Fig. 76-4). Unlike stores of calcium, the readily exchangeable soft tissue stores of phosphate, such as those in muscle, are large.

Figure 76-4. Average daily calcium and phosphate turnover in humans.

Regulation of Calcium and Phosphate Metabolism

The maintenance of calcium and phosphate homeostasis depends on major contributions from three organ systems – the gastrointestinal tract, the skeleton, and the kidneys – with minor contributions from the skin and liver.² The primary hormonal regulators of this metabolism are PTH, vitamin D, and calcitonin. The actions of each of these hormones in the organs are summarized in Table 76-1.

Parathyroid Hormone

PTH is the single most important hormonal regulator of calcium and phosphate metabolism in humans. It has direct effects on the skeleton and kidney and indirect effects on the intestine, mediated through vitamin D. In target tissues, PTH binds first to membrane receptors, activating adenyl cyclase to generate cyclic adenosine monophosphate (cAMP), which regulates other intracellular enzymes.

In bone, the effects of PTH are complex, stimulating both resorption and the formation of new bone. However, sustained elevations of PTH stimulate osteoclasts and inhibit osteoblasts. Osteocytes, in the matrix of cortical bone, may also act to reabsorb matrix in response to PTH, a process referred to as *osteocytic osteolysis*. Calcium and phosphate mobilization in response to PTH occurs in two phases. Initially, mineral is mobilized from areas of rapid equilibrium. This phase is followed by a more sustained release mediated by newly synthesized lysosomal and hydrolytic enzymes. In the kidney, PTH increases the reabsorption of extracellular fluid calcium at any given concentration, although excess secretion, because of hypercalcemia, increases the net daily amount of urinary calcium excretion. Reabsorption in the proximal tubule and loop of Henle is linked with sodium transport such that factors that alter sodium transport concomitantly alter calcium reabsorption. In contrast, reabsorption in the distal nephron is independent of sodium and directly influenced by PTH. PTH also increases phosphate excretion. This action is accompanied by enhanced bicarbonate secretion. PTH probably has only indirect effects on the gastrointestinal tract, by stimulating the hydroxylation of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D in the kidney.

Table 76-1 Hormonal Regulation of Calcium and Phosphate Metabolism

Location	Parathyroid Hormone	Vitamin D	Calcitonin
Gastrointestinal tract	No direct effect	Stimulates calcium and phosphate absorption	No direct effect
Skeleton	Stimulates calcium and phosphate resorption	Stimulates calcium and phosphate resorption	Inhibits calcium and phosphate resorption
Kidneys	Stimulates calcium resorption	No direct effect	Inhibits calcium and phosphate resorption

Figure 76-5. The parathyroid gland produces a precursor of PTH, prepro-PTH, that is sequentially cleaved to pro-PTH and PTH. PTH secretion is controlled by the extracellular fluid calcium concentration.

PTH is synthesized initially as a precursor, preproPTH, which is sequentially cleaved in the parathyroid gland to proPTH and then to PTH (Fig. 76-5). Secretion of this 84-amino-acid molecule is controlled by a negative feedback loop with extracellular fluid calcium. Most PTH is secreted in this form and then cleaved in the liver into N- and C-terminal fragments. The N-terminus contains most of the biologic activity and is rapidly degraded by the liver, whereas the inactive C-terminus is slowly metabolized by the kidney.

Vitamin D

Vitamin D acts at two major sites. It increases intestinal absorption of calcium and phosphate. In addition, in the skeleton, it promotes mineralization and enhances PTH-mediated mobilization of calcium and phosphate. It has no known direct effect on the kidney.

Vitamin D₃, or cholecalciferol, is produced normally by the action of sunlight on 7-dehydrocholesterol in the skin (Fig. 76-6). It is then hydroxylated in the liver (25 position) and kidney (1 position) to form the active 1,25-dihydroxyvitamin D₃ (calcitriol). Vitamin D₂ is normally present in yeast and fungi but not in humans. It is the major pharmacologic source of vitamin D. Pharmaceutical preparations include vitamin D₂ (ergocalciferol), 25-hydroxycholecalciferol (calcifediol), and 1,25-dihydroxycholecalciferol (calcitriol). 1-Hydroxycholecalciferol and dihydrotachysterol are synthetic preparations that require only 25-hydroxylation for activity and so are useful for supplementation in patients with renal failure, who lack the 1-hydroxylase.

Calcitonin

Calcitonin is a 32-amino-acid protein produced by the parafollicular C (calcitonin) cells of the thyroid. The C cells are embryologically derived from the neural crest and, in lower animals, are found in the ultimobranchial bodies, which are glandular structures derived from the lowest branchial pouch. In humans, these structures are incorporated into the superior and lateral aspects of the thyroid lobes.

Total thyroidectomy, with removal of all the C cells, is well tolerated. Calcitonin is not essential for the normal control of calcium metabolism in adult humans. It does inhibit bone resorption and can produce hypocalcemia in experimental animals. It also increases urinary calcium and phosphate excretion. These effects are mediated primarily through cAMP. Several secretagogues for calcitonin have been identified, including catecholamines, gastrin, and cholecystokinin, but the most potent appear

to be calcium and pentagastrin. Exogenously administered calcitonin can be useful pharmacologically to reduce serum calcium levels.

Mineral Homeostasis

Under normal conditions, serum calcium and phosphate levels vary minimally during the course of the day. Regulation occurs primarily through PTH but also through a series of feedback loops involving vitamin D and calcitonin (Fig. 76-7). A fall in serum-ionized calcium increases PTH secretion and stimulates the production of 1,25-dihydroxyvitamin D₃. Conversely, increases in serum calcium inhibit PTH secretion and the formation of active calciferol.

Pathophysiology

Diseases of the parathyroid glands present almost exclusively as disorders of calcium metabolism. Hypercalcemia is the most common manifestation, and in the patient who presents with an elevated serum calcium level, the differential diagnosis can be complex. A thorough understanding of both hypercalcemia and hypocalcemia is essential for the successful treatment of patients undergoing parathyroid surgery. Primary disorders of plasma phosphate are not usually related to surgical disease and are not discussed in detail here.

HYPERCALCEMIA

Hypercalcemia is a relatively common clinical problem.^{3,4} In the general population and in hospital outpatients, the incidence is between 0.1% and 0.5%. Most patients in this group have primary hyperparathyroidism. In contrast, hypercalcemia is identified in almost 5% of hospitalized patients, and nearly two-thirds of them have a malignancy.

Clinical Manifestations

The symptoms of hypercalcemia are varied and nonspecific (Table 76-2). Severity is a function of both the magnitude and rapidity of onset of the hypercalcemia. Many of the manifestations are subtle and are evident only in retrospect, after the patient has been successfully treated for the cause of the elevated calcium. Specific symptoms and diagnostic tests are addressed in more detail in the section on hyperparathyroidism.

Figure 76-6. Schematic illustration of the synthesis of vitamin D₃. Ergosterol, 1-alpha-hydroxyvitamin D₃, and dihydrotachysterol are synthetic preparations of vitamin D.

Differential Diagnosis

Although the diagnosis of primary hyperparathyroidism can, after appropriate investigation, be established with confidence in most patients, all causes of hypercalcemia must be considered and excluded. The multiple causes of hypercalcemia are listed in Table 76-3.

Etiology

Hyperparathyroidism

The diagnosis of hyperparathyroidism is discussed in detail later. Patients typically have elevated plasma concentrations of calcium and PTH, increased urinary excretion of calcium, and a low plasma concentration of phosphate.

Malignancy

Generally, patients with hypercalcemia and malignancy (humoral hypercalcemia of malignancy) can be classified into two groups.⁵⁻⁷ Patients with solid tumors, such as lung carcinoma (25% of all cases of humoral hypercalcemia of malignancy); breast carcinoma (20%); squamous cell carcinoma of the head, neck, esophagus, or female genital tract (19%); or renal cell cancer (8%), account for three-fourths of all cases. Humoral hypercalcemia of malignancy in this setting generally appears late in the disease, with nearly all patients having known, or readily evident, malignancy. These patients have elevated levels of serum calcium, low levels of serum phosphorus, and elevated levels of urinary cAMP, consistent with increased PTH activity but normal or low-serum PTH levels. The hypercalcemia is now known to be caused by PTH-related protein secreted by the tumor, rather than by the bony metastases that many of these patients have because of the advanced nature of their cancers. In the second group, accounting for one-fourth of cases, are patients with hematologic malignancies, such as multiple myeloma, certain lymphomas and leukemias, and a subset of the patients with breast cancer. These patients have elevated levels of serum calcium, but in contrast to most patients with solid tumors and humoral hypercalcemia of malignancy, they have elevated levels of serum phosphate and low levels of urinary cAMP. These patients always have lytic bony lesions and histologically demonstrate increased osteoclast bone resorption adjacent to tumor cells. This osteoclast-activating activity is an effect of cytokines, mainly interleukin-1 beta and tumor necrosis factor-beta (lymphotoxin). These cytokines promote local net bone resorption and thus produce hypercalcemia and hyperphosphatemia.

Figure 76-7. Feedback loops involved in the regulation of serum calcium and phosphorus. PTH, parathyroid hormone; CT, calcitonin.

DIAGNOSIS

Table 76-2 Clinical Features of Hypercalcemia

Neurologic	Cardiovascular
■ Lethargy	■ Electrocardiogram changes (short QT interval, widened T-wave)
■ Confusion	■ Bradycardia
■ Coma	■ Heart block
■ Headache	■ Hypertension
■ Depression	
■ Paranoia	Renal
■ Muscle weakness	■ Polyuria
■ Hyporeflexia	■ Uremia
■ Incontinence	■ Renal colic
■ Memory loss	■ Nephrocalcinosis
■ Hearing loss	
■ Ataxia	Other
Gastrointestinal	■ Band keratopathy
■ Constipation	■ Conjunctivitis
■ Anorexia	■ Change in vision
■ Nausea and vomiting	■ Pruritus
■ Polydipsia	■ Thrombosis
■ Weight loss	■ Myalgia
■ Pancreatitis	
■ Peptic ulcer	
■ Abdominal pain	

Vitamin D and Vitamin A Intoxication

When administered in excess, vitamins A and D can produce hypercalcemia. Affected patients tend to have normal or elevated serum phosphate levels associated with a low PTH level. Metastatic calcification may occur.

Thiazide Diuretics

Thiazides may increase serum calcium levels to a mild degree, primarily through hemoconcentration and decreased renal excretion. Serum phosphate may also be depressed. It often takes several weeks for the hypercalcemia to resolve after the medication is discontinued.

Hyperthyroidism

Hyperthyroidism is associated with increased bone resorption. Often, the plasma PTH is low, and a history of other thyrotoxic symptoms can be elicited. The hypercalcemia usually resolves as the patient becomes euthyroid.

Milk–Alkali Syndrome

Typically, the milk–alkali syndrome occurs in patients with peptic ulcers who consume large quantities of milk and absorbable antacids. Usually, some degree of renal failure is present. PTH levels are low. This syndrome has become much less common with the increased use of nonabsorbable antacids, histamine 2-receptor antagonists, and proton pump inhibitors as therapy for peptic ulcer disease.

ETIOLOGY

Table 76-3 Causes of Hypercalcemia

■ Hyperparathyroidism
■ Malignancy
■ Vitamin A or D intoxication
■ Thiazide diuretics
■ Hyperthyroidism
■ Milk–alkali syndrome
■ Sarcoidosis and other granulomatous diseases
■ Familial hypocalciuric hypercalcemia
■ Immobilization
■ Paget disease
■ Lithium therapy
■ Addisonian crisis
■ Idiopathic hypercalcemia of infancy

Sarcoidosis and Other Granulomatous Diseases

These syndromes are associated with hypersensitivity to vitamin D. The granulomas can convert inactive vitamin D to its active form. Patients have elevated plasma globulins and low PTH levels. The administration of large doses of corticosteroids for 10 days usually reduces the hypercalcemia. Biopsy of lymph nodes or the liver may confirm the diagnosis.

Familial Hypocalciuric Hypercalcemia

This disease is an asymptomatic, autosomal dominant condition characterized by mild to moderate hypercalcemia, hypocalciuria, and normal or only slightly elevated PTH levels. It develops in people heterozygous for a mutation in the calcium-sensing receptor.⁸⁻¹⁰ The mutation causes an increase in the set point for extracellular calcium concentration, so that the “normal” calcium level is higher in these people than in the normal population. No treatment is necessary, although people with this disease should receive genetic counseling. Neonatal severe hyperparathyroidism, which can be fatal, develops in children homozygous for mutations in this receptor. Treatment for neonates with this disease is controversial, but they appear to benefit from early surgical management.

Immobilization

Immobilization produces hypercalcemia by increasing the ratio of bone resorption to bone formation. These patients can usually be distinguished by history, although on laboratory evaluation they have elevated serum levels of calcium and phosphate and a decreased serum concentration of PTH. Often, hypercalciuria is present, which may lead to the development of renal stones. Treatment is early mobilization and forced diuresis.

Other Causes

A variety of other diseases may produce hypercalcemia. For example, Paget disease (osteitis deformans) typically causes mild elevations in serum calcium. Paget disease can be diagnosed on the basis of the characteristic radiographic lesion. Adrenal insufficiency may be associated with hypercalcemia, although the symptoms are typically those of the primary abnormality. Lithium therapy appears to produce hypercalcemia by altering the parathyroid set point for inhibition by calcium, and, over long courses of therapy, may also be associated with hyperparathyroidism. Idiopathic hypercalcemia of infancy is a rare disorder that is probably the result of hypersensitivity to vitamin D. It occurs in infants with mental retardation and is satisfactorily treated with glucocorticoids. Other causes include aluminum-induced renal osteomalacia and a host of analytic errors related to improper specimen collection with prolonged tourniquet times, tube contamination, and instrument drift.

Medical Treatment

Although the choice of therapy is tailored to the cause of the hypercalcemia, several general measures can prove effective.^{11,12}

For the patient with mild hypercalcemia, a trial of a decrease in dietary calcium is indicated. A reduction in intake of milk and other dairy products is suggested, along with discontinuation of thiazide diuretics and vitamin D preparations. Mobilization prevents bone demineralization.

Patients with more marked hypercalcemia or severe symptoms should be admitted to the hospital for treatment, with careful observation and monitoring. In the patient with severe hyperparathyroidism, although the definitive therapy is surgical, it is unwise to proceed with neck exploration until the calcium has been reduced to near-normal levels. The mainstay of therapy is intravenous hydration, preferably with normal saline solution in sufficient quantities to maintain the urine output above 100 mL/hr. These patients are often dehydrated before therapy, and fluid can be administered intravenously at a rate of 200 mL/hr. Caution must be exercised in older patients, whose cardiac reserve may be marginal. This therapy exploits the parallel handling of calcium and sodium by the kidneys. The diuretic furosemide also increases sodium and calcium excretion but should not be used until the patient is well hydrated.

The end points of therapy are a decrease in the serum calcium level and a reduction of symptoms. Diuresis with saline solution is usually effective when the hypercalcemia results from hyperparathyroidism or a benign cause. In contrast, the hypercalcemia of malignancy may produce severe symptoms associated with extremely high serum calcium levels that are difficult to control. In this setting, a variety of other measures may be considered (Table 76-4). Some of the agents used to treat hypercalcemia cause significant toxicity, and close patient monitoring is required during treatment. Calcitonin is a fairly weak hypocalcemic agent, but it acts rapidly and is associated with less toxicity than many of the other drugs.¹² Salmon calcitonin is the most potent preparation. Treatment

with glucocorticoids is particularly efficacious in patients with sarcoidosis and other granulomatous diseases. Plicamycin has proved useful in patients with hypercalcemia of malignancy, but it causes a cumulative toxicity (thrombocytopenia, hepatotoxicity, and nephrotoxicity). Bisphosphonates inhibit osteoclast activity directly. These agents are administered orally or parenterally and are particularly efficacious, although long-term use may be associated with significant osteomalacia.⁷ Prostaglandin synthetase inhibitors were initially considered useful, but their efficacy has proved to be limited. Intravenous phosphates and chelating agents have largely been abandoned because of their severe toxicity; however, oral phosphates may be beneficial in patients requiring prolonged therapy.

HYPOCALCEMIA

Hypocalcemia can occur as a consequence of various acquired and hereditary diseases.¹³ Generally, these disorders produce a deficiency or defect in the action of either PTH or vitamin D. It is most commonly a significant clinical problem after neck operation for thyroid disease. Chronic vitamin D deficiency is associated with compensatory PTH excess. The end result is rickets in children or osteomalacia in adults.

TREATMENT

Table 76-4 Treatment of Hypercalcemia

Therapy of Primary Disease
■ Tumor resection (hypercalcemia of malignancy)
■ Parathyroidectomy (primary hyperparathyroidism)
Expansion of extracellular volume
■ Infusion of saline solution
■ Enhancement of urinary calcium excretion
■ Extracellular volume expansion
■ Loop diuretics (furosemide and ethacrynic acid)
Inhibition of Bone Resorption
■ Calcitonin
■ Glucocorticoids
■ Plicamycin (mithramycin)
■ Bisphosphonates
■ Gallium nitrate
Reduction of Intestinal Calcium Absorption
■ Low-calcium diet
■ Glucocorticoids
Other Treatments
■ Dialysis
■ Mobilization
■ Oral phosphate
■ Estrogens or progestogens (postmenopausal women with primary hyperparathyroidism)
■ Chloroquine (sarcoidosis)

Modified from Attie MF. Treatment of hypercalcemia. *Endocrinol Metab Clin North Am* 1989;18(3):807–828.

Clinical Features

The major signs and symptoms of hypocalcemia are a direct consequence of the reduction in plasma levels of ionized calcium, which increases neuromuscular excitability (Table 76-5). The earliest clinical manifestations are numbness and tingling in the circumoral area, fingers, and toes. Mental symptoms are also common. Patients become anxious, depressed, and occasionally confused. Tetany may develop, characterized by carpopedal spasm, tonic–clonic convulsions, and laryngeal stridor. The magnitude of symptoms at any given plasma concentration of ionized calcium varies from patient to patient. On physical examination, contraction of the facial muscles is elicited by tapping anterior to the ear, over the facial nerve (Chvostek sign), although this sign may be present in 10% of normocalcemic patients. Trousseau sign is elicited by occluding blood flow to the forearm for 3 minutes. The development of carpal spasm indicates hypocalcemia, although the test is unpleasant and clinically impractical.

Etiology

Some of the causes of hypocalcemia are listed in Table 76-6. The most common cause of hypocalcemia by far is excision of or damage to the parathyroid glands during thyroid surgery.

Postoperative Hypoparathyroidism

Postoperative hypoparathyroidism commonly develops after total thyroidectomy.^{13,14} Most patients undergoing operation on the thyroid experience some alteration in serum calcium, although they often are asymptomatic; the low calcium probably represents contusion or temporary alteration of the blood supply to the parathyroid glands. The hypocalcemia is usually transient and is not treated unless significant symptoms develop. Occasionally, in hyperparathyroid patients who have parathyroidectomy and significant bone disease, a marked skeletal deposition of calcium and symptomatic hypocalcemia occurs, the so-called *bone hunger*. The plasma calcium usually reaches its nadir at 48 to 72 hours after surgery and then slowly returns to normal within several days. These patients may require calcium and vitamin D therapy for weeks or months after parathyroidectomy.

DIAGNOSIS

Table 76-5 Clinical Features of Hypocalcemia

Neurologic
■ Circumoral paresthesia
■ Light-headedness
■ Depression
■ Anxiety
■ Confusion
■ Chvostek sign
■ Trousseau sign
■ Irritability
■ Laryngeal spasm
■ Seizures
Musculoskeletal
■ Tetany
■ Cramps
■ Involuntary twitching
■ Osteomalacia
Cardiovascular
■ Electrocardiogram changes (prolonged QT interval, T-wave peaking)
■ Arrhythmia
■ Tachycardia, hypotension
Other Features
■ Lenticular cataracts

Idiopathic Hypoparathyroidism

A less common form of hypoparathyroidism is idiopathic lack of function. It occurs both sporadically and in families. In some cases, it develops as part of a polyglandular disorder and is thought to have an autoimmune basis. DiGeorge syndrome is a group of congenital disorders involving the branchial pouches that produce partial or complete agenesis of the thymus and parathyroid glands. Hypoparathyroidism can also develop in newborns as a result of prenatal suppression of the fetal parathyroid glands as a consequence of maternal hypercalcemia.¹⁵ It is also common in otherwise normal but premature infants.

ETIOLOGY

Table 76-6 Causes of Hypocalcemia

- Hypoparathyroidism
- Vitamin D deficiency
- Pseudohypoparathyroidism
- Hypomagnesemia
- Malabsorption
- Pancreatitis
- Hypoalbuminemia
- Chelation of calcium
- Osteoblastic metastases
- Toxic shock syndrome
- Hyperphosphatemia

Vitamin D Deficiency

Vitamin D deficiency can occur as a result of dietary deficiency or lack of sun exposure. Likewise, renal disease produces a decrease in the 1-hydroxylase activity necessary for the formation of active vitamin D. The result is a decrease in calcium absorption and an increased secretion of PTH by the stimulated parathyroid glands. Osteomalacia, abnormal fractures, and the deformities of rickets may result.

Pseudohypoparathyroidism

Pseudohypoparathyroidism is a familial disease characterized by a rotund appearance, shortening of the extremities, and sometimes mental deficiency. The defect is not in PTH secretion; in fact, most patients have elevated plasma levels of PTH with evidence of increased bone resorption. Rather, the kidney is unresponsive to the hormone, and as a consequence, hypocalcemia and hyperphosphatemia develop. The deficit appears to be in the renal adenyl cyclase system.

Hypomagnesemia

This unusual deficit may result from chronic alcoholism, malabsorption, parenteral nutrition, or increased renal clearance during therapy with aminoglycosides. The deficit appears to block the physical response to PTH in addition to its release from the parathyroid gland.

Other Causes

In short-gut syndrome, after extensive small-bowel resection or bypass, or after some forms of bariatric surgery, vitamin D and calcium may be absorbed in insufficient quantities. In pancreatitis, the massive soft tissue destruction and saponification that occur with hemorrhagic disease may sequester significant amounts of calcium in the retroperitoneum. Some undefined systemic factor also appears to contribute to hypocalcemia in these patients. Hypoalbuminemia causes a reduction in the total plasma calcium level, although the level of ionized calcium remains within the normal range and patients are asymptomatic. Circulatory substances, such as the citrate used to anticoagulate banked blood and radiographic contrast media, may bind to calcium. In patients with osteoblastic metastases, particularly associated with prostate carcinoma, hypocalcemia has been attributed to increased calcium flux into the lesions. Toxic shock syndrome is sometimes associated with hypocalcemia, but the mechanism has not been defined. Acute hyperphosphatemia, as a consequence of exogenous administration of phosphate or during the cytolytic chemotherapy of highly responsive tumors (e.g., Burkitt lymphoma and acute lymphoblastic leukemia), may produce symptomatic hypocalcemia associated with soft tissue calcification.

Treatment

The treatment of hypocalcemia is summarized in [Table 76-7](#). For acute symptomatic hypocalcemia, calcium should be administered intravenously. Calcium gluconate is less irritating to the veins than calcium chloride, and the calcium release is slower, without a risk for overcorrection. Usually, 20 to 30 mL of 10% solution is infused over a 15- to 20-minute period, and then 50 to 100 mL is administered over the next 12 hours in adults. A practical guide after an initial bolus dose includes 60 mL of 10% calcium gluconate in a 500-mL bag of dextrose 5% in water, infused at 1 mL/kg/hr, and adjusted every 4 hours based on the serum level of calcium and patient symptoms. Bicarbonate precipitates any calcium infused through the same intravenous line. Serum magnesium should always be measured, and hypomagnesemia should be corrected if present. In patients with convulsions from advanced tetany, diphenylhydantoin therapy is useful, but symptoms should never be allowed to progress to this point.

TREATMENT

Table 76-7 Treatment of Hypocalcemia

Symptom or Goal	Treatment
Symptomatic hypocalcemia	Oral calcium carbonate or intravenous calcium gluconate, and possibly vitamin D supplements to increase the efficiency of absorption of oral supplements
Symptomatic tetany	Intravenous calcium gluconate
Correction of hypomagnesemia	Intravenous magnesium chloride
Vitamin D supplementation	Ergocalciferol, calcifediol (liver disease), calcitriol (renal disease)
Long-term therapy	Calcium carbonate; low-phosphate, low-oxalate diet; parathyroid grafting (immunosuppressed or cryopreserved autograft)

Long-term therapy is gauged on the basis of symptoms. In the postoperative patient, the continued stimulus of mild hypocalcemia to any remaining parathyroid gland tissue may prove useful. Concomitant therapy with calcium and vitamin D is effective in a timely fashion. A starting dose of 2 g of oral calcium carbonate per day in divided doses is usually well tolerated. Vitamin D can be administered as calcitriol, an active synthetic vitamin D analog. Most adults respond to a dose of 0.5 to 1.0 mcg/day; reduced doses may be necessary for patients with renal dysfunction.

HYPERPARATHYROIDISM

Definitions

Parathyroid neoplasms are rarely identified by physical enlargement but rather are sought because of the peripheral effects of excess hormone. Primary hyperparathyroidism develops spontaneously, without apparent cause but possibly in response to exogenous stimuli. When the normal control of serum calcium is disturbed and the autonomous production of PTH is increased, the state is referred to as *primary hyperparathyroidism*. This category includes both benign single- and multiple-gland enlargements and the much rarer parathyroid carcinoma. In some cases, the disease is familial. In contrast, *secondary hyperparathyroidism* occurs when a defect in mineral homeostasis leads to a compensatory increase in parathyroid function. This occurs most commonly in response to renal disease but may also develop as a consequence of the hypocalcemia associated with some diseases of the gastrointestinal tract, bones, or other endocrine organs. Occasionally, with prolonged secondary stimulation, the hyperfunctioning glands are no longer physiologically responsive to an increase in ionized calcium. This uncommon (affecting about 2% of patients after renal transplantation), relatively autonomous state referred to as *tertiary hyperparathyroidism*, develops most commonly after renal transplantation when the renal defect in calcium homeostasis is corrected.

Incidence

The advent in the 1970s of the widespread assessment of serum calcium as part of automated multichannel analysis has considerably altered our understanding of hyperparathyroidism. Before that time, primary hyperparathyroidism was thought to be a relatively rare condition. Most patients presented with symptoms of disease, usually renal stones or bony manifestations. Currently, most patients are asymptomatic or have only vague symptoms or signs that can be related to hyperparathyroidism.^{16,17} Occasionally, patients recognize that they had symptoms only after their well-being improves following parathyroidectomy. Incidence varies with both age and gender (Table 76-8), but hyperparathyroidism is believed to develop in about 50 to 100 people per 100,000 in the general population, with approximately 50,000 new cases occurring annually in the United States.¹⁸ Marked variations have been noted worldwide; the reasons for these differences remain unclear.

Table 76-8 Age-Specific and Gender-Specific Incidence of Primary Hyperparathyroidism

Age (yrs)	New Cases Per 100,000	
	Men	Women
<39	5	8
40–50	26	104
>60	92	189
Total	18	56

Adapted from Heath H III, Hodgson SF, Kennedy MA. Primary hyperthyroidism: incidence, morbidity, and potential economic impact in a community. *N Engl J Med* 1980;302:189.

Etiology

The cause of primary hyperparathyroidism is not known. Although the sequence of progression from secondary to tertiary disease in response to chronic stimulation has a logical appeal, it is difficult to draw parallels with primary disease. Most patients with primary hyperparathyroidism have disease of a single rather than of multiple glands, which is not what might be predicted if an external stimulus were part of the pathophysiology. Hyperparathyroidism is most common in postmenopausal women, the population group with the highest incidence of osteoporosis and the most significant alterations in calcium and phosphate metabolism. Loss of renal function with aging is associated with elevations in PTH and decreases in phosphate clearance. It has been suggested but not demonstrated that a renal calcium leak, if sufficient, might result in a chronic calcium deficit stimulating the parathyroid glands.

Genetic studies of parathyroid adenomas have described an oncogene (*PRAD1*) that may be one step in the path to neoplasia in these tumors. Overexpression of the normal *PRAD1* gene, also known as *cyclin D1*, allows progression of the cell cycle from the G1 phase to the S phase, thus promoting cellular growth and division. *PRAD1* is overexpressed in 20% to 40% of parathyroid adenomas; further research may reveal other genetic alterations that contribute to the neoplastic growth. The *MEN1* tumor-suppressor gene has also been implicated in the molecular pathogenesis of sporadic hyperparathyroidism. About 15% to 20% of sporadic parathyroid adenomas have either somatic mutation or biallelic deletion of the *MEN1* gene.^{19,20}

Hyperparathyroidism occurs in several familial forms. It is a major component of the multiple endocrine neoplasia (MEN) syndromes types 1 and 2A. The parathyroid disease of MEN-1 syndrome is multiple parathyroid adenomas that appear with increasing frequency over the patient's lifetime.²¹ In other families, hyperparathyroidism is inherited in an autosomal dominant fashion without other manifestations of MEN-1 or MEN-2; some have osseous abnormalities (tumor–jaw syndrome) and some apparently have isolated disease.

Figure 76-8. Parathyroid adenoma. The tumor consists of sheets of neoplastic chief cells and is separated from normal parenchyma by a thin capsule.

Pathology

Single-Gland Versus Multiple-Gland Disease

Microscopically, the cell most commonly involved in primary hyperparathyroidism is the chief cell. Less frequently, the oxyphil cell is the predominant cell type. Diseased glands typically have an increase in the proportion of stromal cells and a reduction in the proportion of stromal fat. Single diseased glands, or adenomas, have been classically described with a predominance of chief cells centering in a single focus, with a compressed rim of surrounding normal tissue (Fig. 76-8). In contrast, parathyroid
